component of shear stress normally written as σ_{12} (not to be confused with surface tension, for which the symbol σ has been used above). Figure 52B shows, in elevation, an enlarged view of an infinitesimal element of the fluid of cubic shape, and the directions of the forces experienced by this cube associated with σ_{12} are indicated by arrows. Other arrows show the directions of the forces associated with the so-called normal stresses σ_{11} and σ_{22}, which in the absence of motion of the fluid would both be equal, by Pascal's law, to $-p$. Now σ_{12} is clearly zero when the rate of variation of velocity, $\partial v_1/\partial x_2$, is zero, for then there is no slip, and presumably it increases monotonically as $\partial v_1/\partial x_2$ increases. Newton made the plausible assumption that the two are linearly related—*i.e.*, that

$$\sigma_{12} = \eta\left(\frac{\partial v_1}{\partial x_2}\right). \tag{147}$$

The full name for the coefficient η is shear viscosity to distinguish it from the bulk viscosity, b, which is defined below. The word shear, however, is frequently omitted in this context.

Now if the only shear stress acting on the cubic element of fluid sketched in Figure 52B were σ_{12}, the cube would experience a torque tending to make it twist in a clockwise sense. Since the magnitude of the torque would vary like the third power of the linear dimensions of the cube, whereas the moment of inertia of the element would vary like the fifth power, the resultant angular acceleration for an infinitesimal cube would be infinite. One may infer that any tendency to twist in a clockwise sense gives rise instantaneously to an additional shear stress σ_{21}, the direction of which is indicated in the diagram, and that σ_{12} and σ_{21} are equal at all times. It follows that equation (147) cannot be a complete expression for these shear stresses, for it does not include the possibility that the fluid is moving in the x_2 direction, with a velocity v_2 that varies with x_1. The complete expression for what is called a Newtonian fluid is

$$\sigma_{12} = \sigma_{21} = \eta\left[\left(\frac{\partial v_1}{\partial x_2}\right) + \left(\frac{\partial v_2}{\partial x_1}\right)\right]. \tag{148}$$

Similar expressions may be written down for σ_{23} $(= \sigma_{32})$ and σ_{31} $(= \sigma_{13})$. Since Newton's day these hypothetical expressions have been fully substantiated for gases and simple liquids, not only by experiment but also by analysis of the molecular motions and molecular interactions in such fluids undergoing shear, and for such fluids one can even predict the magnitude of η with reasonable success. There do exist, however, more complicated fluids for which the Newtonian description of shear stress is inadequate, and some of these are very familiar in the home. In the whites of eggs, for example, and in most shampoos, there are long-chain molecules that become entangled with one another, and entanglement may hinder their efforts to respond to changes of environment associated with flow. As a result, the stresses acting in such fluids may reflect the deformations experienced by the fluid in the recent past as much as the instantaneous rate of deformation. Moreover, the relation between stress and rate of deformation may be far from linear. Non-Newtonian effects, interesting though they are, lie outside the scope of the present discussion, however.

Non-Newtonian effects

The sort of velocity profile that is suggested by Figure 52B may be established by containing the fluid between two parallel flat plates and moving one plate relative to the other. The possibility exists that in this situation the layers of fluid immediately in contact with each plate will slip over them with some finite velocity (indicated in the diagram by an arrow labeled v_{slip}). If so, the frictional stresses associated with this slip must be such as to balance the shear stress $\eta(\partial v_1/\partial x_2)$ exerted on each of these layers by the rest of the fluid. Little is known about fluid-solid frictional stresses, but intelligent guesswork suggests that they are proportional in magnitude to v_{slip} and that, in the circumstances to which Figure 52A refers, the distance d below the surface of the stationary bottom plate at which the straight line representing the variation of v_1 with x_2 extrapolates to zero should be of the same order of magnitude as the diameter of a molecule if the fluid is a liquid or as the molecular "mean free path" if it is a gas. These distances are normally very small compared with the separation of the plates, D. Accordingly, fluid flow patterns may normally be treated as subject to the boundary condition that at a fluid-solid interface the relative velocity of the fluid is zero. No reliable evidence for failure of predictions based on this no-slip boundary condition has yet been found, except in the case of what is called Knudsen flow of gases (*i.e.*, flow at such low pressures that the mean free path is comparable in length with the dimensions of the apparatus).

If a fluid is flowing steadily between two parallel plates that are both stationary and if its velocity must be zero in contact with both of them, the velocity profile must necessarily have the form indicated in Figure 53. A force in the forward direction due to the shear stress $\eta(\partial v_1/\partial x_2)$ is transmitted to the plates, and an equal force in the

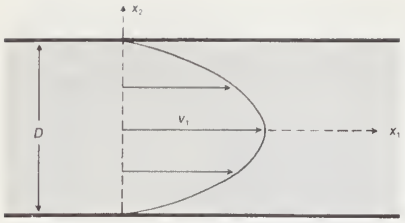

Figure 53: Velocity profile for laminar flow between two plates (or inside a cylindrical tube), driven by a pressure gradient (see text).

backward direction acts on the fluid. The motion therefore cannot be maintained unless the pressure acting on the fluid is greater on the left of the diagram than it is on the right. A full analysis shows the velocity profile to be parabolic, and it indicates that the rate of discharge is related to the pressure gradient by the equation

$$Q = -\left(\frac{WD^3}{12\eta}\right)\left(\frac{dp}{dx_1}\right), \tag{149}$$

where W ($>> D$) is the width of the plates, measured perpendicular to the diagram in Figure 53. A similar analysis of the problem of steady flow through a (horizontal) cylindrical pipe of uniform diameter D, to which Figure 53 could equally well apply, shows the rate of discharge in this case to be given by

$$Q = -\left(\frac{\pi D^4}{128\eta}\right)\left(\frac{dp}{dx_1}\right); \tag{150}$$

Poiseuille's equation

this famous result is known as Poiseuille's equation, and the type of flow to which it refers is called Poiseuille flow.

Viscosity may affect the normal stress components, σ_{11}, σ_{22}, and σ_{33}, as well as the shear stress components. To see why this is so, one needs to examine the way in which stress components transform when one's reference axes are rotated. Here, the result will be stated without proof that the general expression for σ_{11} consistent with (148) is

$$\sigma_{11} = -p + \left(b + \frac{4\eta}{3}\right)\left(\frac{\partial v_1}{\partial x_1}\right) + \left(b - \frac{2\eta}{3}\right)\left(\frac{\partial v_2}{\partial x_2}\right) + \left(b - \frac{2\eta}{3}\right)\left(\frac{\partial v_3}{\partial x_3}\right). \tag{151}$$

On the right-hand side of this equation, p represents the equilibrium pressure defined in terms of local density and temperature by the equation of state, and b is another viscosity coefficient known as the bulk viscosity.

The bulk viscosity is relevant only where the density is changing. Thus it plays a role in attenuating sound waves in fluids and may be estimated from the magnitude of the attenuation. If the fluid is effectively incompressible, however, so that changes of density may be ignored, the flow is everywhere subject to the continuity condition that

$$\left(\frac{\partial v_1}{\partial x_1}\right) + \left(\frac{\partial v_2}{\partial x_2}\right) + \left(\frac{\partial v_3}{\partial x_3}\right) [\equiv \nabla \cdot \boldsymbol{v} \text{ or div } \boldsymbol{v}] = 0. \tag{152}$$

The terms in (151) that involve b then cancel, and the expression simplifies to

$$\sigma_{11} = -p + 2\eta\left(\frac{\partial v_1}{\partial x_1}\right). \tag{153}$$

Similar equations may be written down for σ_{22} and σ_{33}. These simpler expressions provide the basis for the argument that follows, and the bulk viscosity can be left on one side.

A variety of methods are available for the measurement of shear viscosity. One standard method involves measurement of the pressure gradient along a pipe for various rates of flow and application of Poiseuille's equation. Other methods involve measurement either of the damping of the torsional oscillations of a solid disk supported between two parallel plates when fluid is admitted to the space between the plates, or of the effect of the fluid on the frequency of the oscillations.

The Couette viscometer deserves a fuller explanation. In this device, the fluid occupies the space between two coaxial cylinders of radii a and b ($> a$); the outer cylinder is rotated with uniform angular velocity ω_0, and the resultant torque transmitted to the inner stationary cylinder is measured. If both the terms on the right-hand side of equation (148) are taken into account, the shear stress in the circulating fluid is found to be proportional to $r(d\omega/dr)$ rather than to (dv/dr)—not an unexpected result, since it is only if ω, the angular velocity of the fluid, varies with radius r that there is any slip between one cylindrical lamina of fluid and the next. The torque transmitted through the fluid is therefore proportional to $r^3(d\omega/dr)$. In the steady state, the opposing torques acting on the inner and outer surfaces of each cylindrical lamina of fluid must be of equal magnitude—otherwise the laminae accelerate—and this means that $r^3(d\omega/dr)$ must be independent of r. There are two basic modes of motion for a circulating fluid that satisfy this condition: in one, the liquid rotates as a solid body would, with an angular velocity that does not vary with r, and the torque is everywhere zero; in the other, ω varies like r^{-2}. The angular velocity of the fluid in a Couette viscometer can be viewed as a mixture of these two modes in proportions that satisfy the boundary conditions at $r = a$ and $r = b$. The torque transmitted per unit length of the cylinders turns out to be given by

$$4\pi\eta\omega_0\left[\frac{b^2a^2}{(b^2 - a^2)}\right]. \tag{154}$$

It may be added that if the inner cylinder is absent, the steady flow pattern consists only of the first mode—*i.e.*, the fluid rotates like a solid body with uniform angular velocity ω_0. If the outer cylinder is absent, however, and the inner one rotates, it then consists only of the second mode. The angular velocity falls off like r^{-2}, and the velocity v falls off like r^{-1}.

In the equation of motion given in the following section, the shear viscosity occurs only in the combination (η/ρ). This combination occurs so frequently in arguments of fluid dynamics that it has been given a special name—kinetic viscosity. The kinetic viscosity at normal temperatures and pressures is about 10^{-6} square metre per second for water and about 1.5×10^{-5} square metre per second for air.

Kinetic viscosity

NAVIER-STOKES EQUATION

One may have a situation where σ_{11} increases with x_1. The force that this component of stress exerts on the right-hand side of the cubic element of fluid sketched in Figure 52B will then be greater than the force in the opposite direction that it exerts on the left-hand side, and the difference between the two will cause the fluid to accelerate along x_1. Accelerations along x_1 will also result if σ_{12} and σ_{13} increase with x_2 and x_3, respectively. These accelerations, and corresponding accelerations in the other two directions, are described by the equation of motion of the fluid. For a fluid moving so slowly compared with the speed of sound that it may be treated as incompressible and in which the variations of temperature from place to place are insufficient to cause significant variations in the shear viscosity η, this equation takes the form

$$-\nabla\left(\frac{p}{\rho} + gz\right) - \left(\frac{\eta}{\rho}\right)[\nabla \times (\nabla \times \boldsymbol{v})] = \frac{D\boldsymbol{v}}{Dt} = \frac{\partial \boldsymbol{v}}{\partial t} + (\boldsymbol{v} \cdot \nabla)\boldsymbol{v}. \tag{155}$$

Euler derived all the terms in this equation except the one on the left-hand side proportional to (η/ρ), and without that term the equation is known as the Euler equation. The whole is called the Navier-Stokes equation.

The equation is written in a compact vector notation which many readers will find totally impenetrable, but a few words of explanation may help some others. The symbol ∇ represents the gradient operator, which, when preceding a scalar quantity X, generates a vector with components $(\partial X/\partial x_1, \partial X/\partial x_2, \partial X/\partial x_3)$. The vector product of this operator and the fluid velocity $\boldsymbol{v}$—*i.e.*, $(\nabla \times \boldsymbol{v})$—is sometimes designated as ***curl*** $\boldsymbol{v}$ [and $\nabla \times (\nabla \times \boldsymbol{v})$ is also ***curl curl*** $\boldsymbol{v}$]. Another name for $(\nabla \times \boldsymbol{v})$, which expresses particularly vividly the characteristics of the local flow pattern that it represents, is vorticity. In a sample of fluid

Vorticity

that is rotating like a solid body with uniform angular velocity ω_0, the vorticity lies in the same direction as the axis of rotation, and its magnitude is equal to $2\omega_0$. In other circumstances the vorticity is related in a similar fashion to the local angular velocity and may vary from place to place. As for the right-hand side of (155), Dv/Dt represents the rate of change of velocity that one would see if the motion of a single element of the fluid could be followed—that is, it represents the acceleration of the element—while $\partial v/\partial t$ represents the rate of change at a fixed point in space. If the flow is steady, then $\partial v/\partial t$ is everywhere zero, but the fluid may be accelerating all the same, as individual fluid elements move from regions where the streamlines are widely spaced to regions where they are close together. It is the difference between Dv/Dt and $\partial v/\partial t$—*i.e.*, the final $(v \cdot \nabla)v$ term in (155)—that introduces into fluid dynamics the nonlinearity that makes the subject so rife with surprises.

POTENTIAL FLOW

This section is concerned with an important class of flow problems in which the vorticity is everywhere zero, and for such problems the Navier-Stokes equation may be greatly simplified. For one thing, the viscosity term drops out of it. For another, the nonlinear term, $(v \cdot \nabla)v$, may be transformed into $\nabla(v^2/2)$. Finally, it may be shown that, when $(\nabla \times v)$ is zero, one may describe the velocity by means of a scalar potential φ, using the equation

$$v = \nabla\varphi \ [\equiv \text{grad } \varphi]. \tag{156}$$

Thus (155) becomes

$$-\nabla\left(\frac{p}{\rho} + gz + \frac{v^2}{2} + \frac{\partial\varphi}{\partial t}\right) = 0,$$

which may at once be integrated to show that

$$\left(\frac{p}{\rho} + gz + \frac{v^2}{2} + \frac{\partial\varphi}{\partial t}\right) = \text{constant}. \tag{157}$$

This result incorporates Bernoulli's law for an effectively incompressible fluid ([133]), as was to be expected from the disappearance of the viscosity term. It is more powerful than (133), however, because it can be applied to nonsteady flow in which $\partial\varphi/\partial t$ is not zero and because it shows that in cases of potential flow the left-hand side of (157) is constant everywhere and not just constant along each streamline.

Thomson's theorem

Vorticity-free, or potential, flow would be of rather limited interest were it not for the theorem, first proved by Thomson, that, in a body of fluid which is free of vorticity initially, the vorticity remains zero as the fluid moves. This theorem seems to open the door for relatively painless solutions to a great range of problems. Consider, for example, a stream of fluid in uniform motion approaching an obstacle of some sort. Well upstream of the obstacle the fluid is certainly vorticity-free, so it should, according to Thomson's theorem, be vorticity-free around the obstacle and downstream as well. In this case a flow potential should exist; and, if the fluid is effectively incompressible, it follows from equations (152) and (156) that it satisfies Laplace's equation,

$$\left(\frac{\partial^2\varphi}{\partial x_1^2}\right) + \left(\frac{\partial^2\varphi}{\partial x_2^2}\right) + \left(\frac{\partial^2\varphi}{\partial x_3^2}\right) \ [\equiv \nabla^2\varphi] = 0. \tag{158}$$

This is perhaps the most frequently occurring differential equation in physics, and methods for solving it, subject to appropriate boundary conditions, are very well established. Given a solution for φ, the fluid velocity v follows at once, and one may then discover how the pressure varies with position and time from equation (157).

The physicists and mathematicians who developed fluid dynamics during the 19th century relied heavily on this reasoning. They based splendid achievements upon it, a notable example being the theory of waves on deep water (see below). There was a touch of unreality, however, about some of their theorizing. If carried to extremes, the argument of the previous section implies that water initially stationary in a beaker can never be set into rotation by rotating the beaker or by stirring it with a spoon, and this is clearly nonsense. It suggests that vorticity-free water remains vorticity-free if it is squeezed into a narrow pipe, and this too is plainly nonsensical, for the well-established parabolic profile illustrated by Figure 53 is not vorticity-free. What is misleading about the argument in situations like these is that it pays inadequate attention to what happens at interfaces. Following the work of Prandtl, physicists now appreciate that vorticity is liable to be fed into the fluid at interfaces, whether these are interfaces between the fluid and some solid object or the free surfaces of a liquid. Once the slightest trace of vorticity is present, it destroys the conditions on which the proof of Thomson's theorem depends. Moreover, vorticity admitted at interfaces spreads into the fluid in much the same way that a dye would spread, and whether or not the results of potential theory are useful depends on how much of the fluid is contaminated in the particular circumstances under discussion.

POTENTIAL FLOW WITH CIRCULATION; VORTEX LINES

The proof of Thomson's theorem depends on the concept of circulation, which Thomson introduced. This quantity is defined for a closed loop which is embedded in, and moves with, the fluid; denoted by K, it is the integral around the loop of $v \cdot dl$, where dl is an element of length along the loop. If the vorticity is everywhere zero, then so is the circulation around all possible loops, and vice versa. Thomson showed that K cannot change if the viscous term in (155) contributes nothing to the local acceleration, and it follows that both K and vorticity remain zero for all time.

Reference was made earlier to the sort of steady flow pattern that may be set up by rotating a cylindrical spindle in a fluid; the streamlines are circles around the spindle, and the velocity falls off like r^{-1}. This pattern of flow occurs naturally in whirlpools and typhoons, where the role of the spindle is played by a "core" in which the fluid rotates like a solid body; the axis around which the fluid circulates is then referred to as a vortex line. Each small element of fluid outside the core, if examined in isolation for a short interval of time, appears to be undergoing translation without rotation, and the local vorticity is zero. Were it not so, the viscous torques would not cancel and the flow pattern would not be a steady one. Nevertheless, the circulation is not zero if the loop for which it is defined is one that encloses the spindle or core. In such situations, a potential that obeys Laplace's equation outside the spindle or core can be found, but it is no longer, to use a technical term that may be familiar to some readers, single-valued.

Vortex lines

Readers who recognize this term are likely to have encountered it in the context of electromagnetism, and it is worth remarking that all the results of potential flow theory have electromagnetic analogues, in which streamlines become the lines of force of a magnetic field and vortex lines become lines of electric current. The analogy may be illustrated by reference to the Magnus effect.

Magnus effect

This effect (named for the German physicist and chemist H.G. Magnus, who first investigated it experimentally) arises when fluid flows steadily past a cylindrical spindle, with a velocity that at large distances from the spindle is perpendicular to the spindle's axis and uniformly equal to, say, v_0, while the spindle itself is steadily rotated. Rotation is communicated to the fluid, and in the steady state the circulation around any loop that encloses the spindle (and encloses a layer of fluid adjacent to the spindle within which the vorticity is nonzero and potential theory is inapplicable) has some nonzero value K. The streamlines that describe the steady flow pattern (outside that "boundary layer") have the form suggested by Figure 54, though the details naturally depend on the magnitude of v_0 and K. The flow pattern has stagnation points at P and P′ and, since the pressure is high at such points, the spindle may be expected to experience a downward force perpendicular both to its axis and to the direction of v_0. Detailed calculations confirm this expectation and show that the magnitude of the force, per unit length of the spindle, is

$$\rho v_0 K \tag{159}$$

This so-called Magnus force is directly analogous to the force that a transverse magnetic field B_0 exerts upon a wire

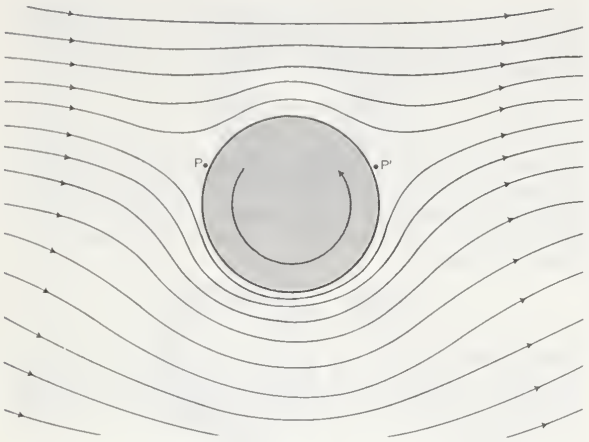

Figure 54: Streamlines for potential flow with circulation past a rotating cylinder. The cylinder experiences a downward Magnus force (see text).

carrying an electric current I, the magnitude of which, per unit length of the wire, is $B_0 I$.

The Magnus force on rotating cylinders has been utilized to propel experimental yachts, and it is closely related to the lift force on airfoils that enables airplanes to fly (see below *Lift*). The transverse forces that cause spinning balls to swerve in flight are, however, not Magnus forces, as is sometimes asserted. They are due to the asymmetrical nature of the eddies that develop at the rear of a spinning sphere (see below *Boundary layers and separation*). Cricket balls, unlike the balls used for baseball, tennis, and golf, have a raised equatorial seam that plays an important part in making the eddies asymmetric. A bowler in cricket who wants to make the ball swerve imparts spin to it, but he does so chiefly to ensure that the orientation of this seam remains steady as the ball moves toward the batsman.

It may be shown, by reference to the magnetic analogue or in other ways, that straight vortex lines of equal but opposite strength, $\pm K$, which are parallel and separated by a distance d, will drift sideways together through the fluid at a speed given by $K/2\pi d$. Similarly, a vortex line that has joined up on itself to form a closed vortex ring of radius a drifts along its axis with a speed given by

$$\left(\frac{K}{4\pi a}\right)\ln\left(\frac{a}{c}\right), \tag{160}$$

where c is the radius of the line's core, with ln standing for natural logarithm. This formula applies, for example, to smoke rings. The fact that such rings slow down as they propagate can be explained in terms of the increase of c with time, due to viscosity.

WAVES ON DEEP WATER

One particular solution of Laplace's equation that describes wave motion on the surface of a lake or of the ocean is

$$\varphi = \varphi_0 \cos\left\{2\pi\left[\left(\frac{x}{\lambda}\right) - ft\right]\right\}\sinh\left[2\pi\frac{(D+z)}{\lambda}\right]. \tag{161}$$

In this case the x-axis is the direction of propagation and the z-axis is vertical; $z = 0$ describes the free surface of the water when it is undisturbed and $z = -D$ describes the bottom surface; φ_0 is an arbitrary constant that determines the amplitude of the motion; and f is the frequency of the waves and λ their wavelength. If λ is more than a few centimetres, surface tension is irrelevant and the pressure in the liquid just below its free surface is atmospheric for all values of x. It can be shown that in these circumstances the wave motion described by (161) is consistent with (157) only if the frequency and wavelength are related by the equation

$$f^2 = \left(\frac{2\pi g}{\lambda}\right)\tanh\left(\frac{2\pi D}{\lambda}\right), \tag{162}$$

and an expression for the speed of the waves may be deduced from this, since $V = f\lambda$. For shallow water ($D << \lambda$) one obtains the answer already quoted as equation (138), but for deep water ($D >> \lambda$) the answer is

$$V = \sqrt{\left(\frac{g\lambda}{2\pi}\right)}. \tag{163}$$

Dispersive character of waves on deep water

Waves on deep water are evidently dispersive, and surfers rely on this fact. A storm in the middle of the ocean disturbs the surface in a chaotic way that would be useless for surfing, but as the component waves travel toward the shore they separate; those with long wavelengths move ahead of those with short wavelengths because they travel faster. As a result, the waves seem nicely regular by the time that they arrive.

Anyone who has observed the waves behind a moving ship will know that they are confined to a V-shaped area of the water's surface, with the ship at its apex. The waves are particularly prominent on the arms of the V, but they can also be discerned between these arms where the wave crests curve in the manner indicated in Figure 55. It seems to be widely believed that the angle of the V becomes more acute as the boat speeds up, much in the way that the conical shock wave accompanying a supersonic projectile becomes more acute (see Figure 51). That is not the case; the dispersive character of waves on deep water is such that the V has a fixed angle of $2\sin^{-1}(1/3) = 39°$. Thomson (Lord Kelvin) was the first to explain this, and so the V-shaped area is now known as the Kelvin wedge.

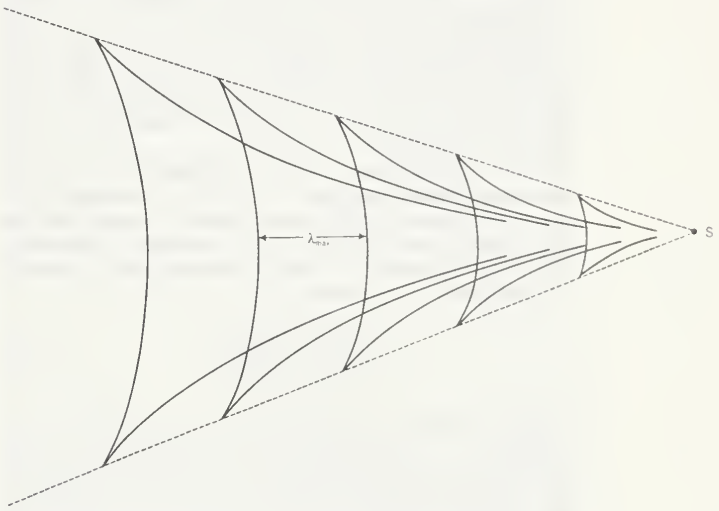

Figure 55: Wave crests in the Kelvin wedge behind a source S that is moving steadily from left to right. The maximum wavelength λ_{max} depends on the speed of the source, but the angle of the wedge does not (see text).

A version of Thomson's argument is illustrated by the diagram in Figure 56. Here S (the "source") represents the bow of the ship which is moving from left to right with uniform speed U, and the lines labeled C, C′, C″, etc., represent a set of parallel wave crests which are also moving from left to right. It can be shown that S will create this set of crests if, but only if, it rides continuously on the one labeled C. (It also can be shown that, though the crests in the set continue indefinitely to the left of C, there can be none to the right of this one.) The condition that S and C move together indicates that there is a relation between wavelength λ and inclination α expressed by the equation

$$\sin\alpha = \frac{V}{U} = \sqrt{\frac{g\lambda}{2\pi U^2}}. \tag{164}$$

This condition can evidently be satisfied by many other sets of crests besides the one represented by full lines in the figure—*e.g.*, by the set with slightly shorter wavelength λ' that is represented by broken lines. When one takes into consideration all the sets that satisfy (164) and have wavelengths intermediate between λ and λ', it becomes apparent that over most of the area behind the source they interfere destructively. They reinforce one another, however, near the intersections that are ringed in the figure. These intersections lie on a line through S of inclination β, where

$$\tan\beta = \frac{\tan\alpha}{(2 + \tan^2\alpha)}. \tag{165}$$

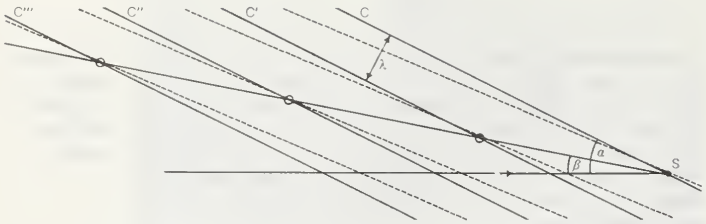

Figure 56: The curved wave crests of Figure 55 result from the superposition of many sets of straight wave crests like the two shown here. These two sets and others that are intermediate in wavelength reinforce one another near the line of inclination β and interfere destructively elsewhere.

It follows that, though the angle α can take any value between 90° (corresponding to $\lambda = \lambda_{max} = 2\pi U^2/g$) and zero, $\tan\beta$ can never exceed $\frac{1}{2}\sqrt{2}$, and $\sin\beta$ can never exceed $\frac{1}{3}$.

Ships lose energy to the waves in the Kelvin wedge, and they experience additional resistance on that account. The resistance is particularly high when the wave system created by the bow, where water is pushed aside, reinforces the wave system created by the "anti-source" at the stern, where the water closes in again. Such reinforcement is liable to occur when the effective length of the boat, L, is equal to $(2n+1)\lambda_{max}/2$ (with $n = 0, 1, 2, \ldots$) and therefore when the Froude number, $U/\sqrt{(Lg)}$, takes one of the values $[\sqrt{(2n+1)\pi}]^{-1}$. However, once a boat has been accelerated past $U = \sqrt{(Lg/\pi)}$, the bow and stern waves tend to cancel, and the resistance resulting from wave creation diminishes.

Waves on deep water whose wavelength is a few centimetres or less are generally referred to as ripples. In such waves, the pressure differences across the curved surface of the water associated with surface tension (see equation [129]) are not negligible, and the appropriate expression for their speed of propagation is

$$V = \sqrt{\left[\left(\frac{g\lambda}{2\pi}\right) + \left(\frac{2\pi\sigma}{\lambda\rho}\right)\right]}. \qquad (166)$$

The wave velocity is therefore large for very short wavelengths as well as for very long ones. For water at normal temperatures, V has a minimum value of about 0.23 metre per second where the wavelength is about 17 millimetres, and it follows (note that equation [164] has no real root for α unless U exceeds V) that an object moving through water can create no ripples at all unless its speed exceeds 0.23 metre per second. A wind moving over the surface of water likewise creates no ripples unless its speed exceeds a certain critical value, but this is a more complicated phenomenon, and the critical speed in question is distinctly higher.

BOUNDARY LAYERS AND SEPARATION

It should be reiterated that vorticity is liable to enter a fluid that is initially undergoing potential flow where it makes contact with a solid and also at its free surface. The way in which, having entered, it spreads, may be illustrated by a simple example. Consider a large body of fluid, initially stationary, being set into motion by the movement in its own plane of a large solid plate that is immersed within the fluid. The motion is communicated from solid to fluid by the frictional forces that prevent slip between the two (see above *Viscosity*), and a velocity profile of the form suggested by Figure 57 is established. Its development with time turns out to be described by the partial differential equation

$$\rho\left(\frac{\partial v_1}{\partial t}\right) = \eta\left(\frac{\partial^2 v_1}{\partial x_2^2}\right). \qquad (167)$$

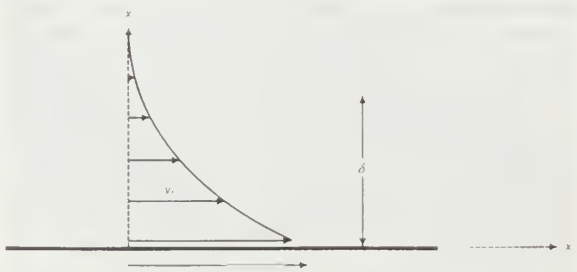

Figure 57: Velocity profile established by motion of a plate through stationary fluid (see text).

In this situation the vorticity, which may be denoted by the symbol Ω, has one nonzero component, directed along the axis perpendicular to the diagram in Figure 57: it is $\Omega_3 = -(\partial v_1/\partial x_2)$. Differentiation of (167) with respect to x_2 shows at once that

$$\rho\left(\frac{\partial \Omega_3}{\partial t}\right) = \eta\left(\frac{\partial^2 \Omega_3}{\partial x_2^2}\right). \qquad (168)$$

This is a diffusion equation. It indicates that, if the plate oscillates to and fro with frequency f, then the so-called boundary layer within which Ω_3 is nonzero has a thickness δ given by

Diffusion equation

$$\delta \approx \sqrt{\left(\frac{\eta}{\pi\rho f}\right)}. \qquad (169)$$

and in most instances of oscillatory motion this is small enough for the boundary layer to be neglected. For example, the boundary layer on the surface of the ocean has a thickness of less than one millimetre when a wave with a frequency of about one hertz passes by; because the effects of viscosity are confined to this layer, they are too slight to affect the propagation of the wave to any significant degree. If the plate is kept moving at a uniform rate, however, the thickness of the boundary layer, as described by (168), will increase with the time t that has elapsed since the motion of the plate began, according to the equation

$$\delta \approx \sqrt{\left(\frac{2\eta t}{\rho}\right)}. \qquad (170)$$

Prandtl suggested that when a stream of fluid flows steadily past an obstacle of finite extent, such as a sphere, the time that matters is the time for which fluid on a streamline just outside the boundary layer remains in contact with it. This time is of order D/v_0, where D is the diameter of the sphere and v_0 is the speed of the fluid well upstream. Hence, one would expect the thickness of the boundary layer at the rear of the sphere to be something like

$$\sqrt{\left(\frac{\eta D}{\rho v_0}\right)}. \qquad (171)$$

If the velocity v_0 is so low that (170) is comparable with or greater than the diameter D, the flow pattern must be so contaminated by vorticity that the neglect of viscosity and reliance on Bernoulli's equation and on the other results of potential theory is clearly unjustified. If the velocity is high and (171) is much less than D, however, the boundary layer would seem to be of little importance. Surely then the results of potential theory are to be trusted?

Alas, that optimistic conclusion is not confirmed by experiment. What happens at high velocities is that the boundary layer comes unstuck from the surface of the sphere—it is said to separate. The reason why it does so is suggested by Figure 58A, which shows the streamlines to be expected when the boundary layer (shown in this figure by a shaded area still attached to the sphere) is relatively thin. Evidently the fluid velocity is higher near the equator of the sphere, at Q, than it is at either of the two poles, P and P′. Thus according to Bernoulli's equation, which can be relied on outside the boundary layer, the pressure near Q is less than it is near P and P′. The pressure gradient acts on the fluid in the boundary layer, accelerating it between P and Q but decelerating it between Q and P′. As the flow velocity increases, so does the pressure gradient, and at a certain stage the decelerating effect between Q and P′ becomes so large that the direction of flow within the boundary layer reverses in sign near the point labeled R in the diagram. The backflow of fluid near R causes an accumulation of fluid that obliges the oncoming boundary layer to separate, and the fluid behind the sphere circulates slowly within the boundary layer as a ring-shaped eddy (Figure 58B).

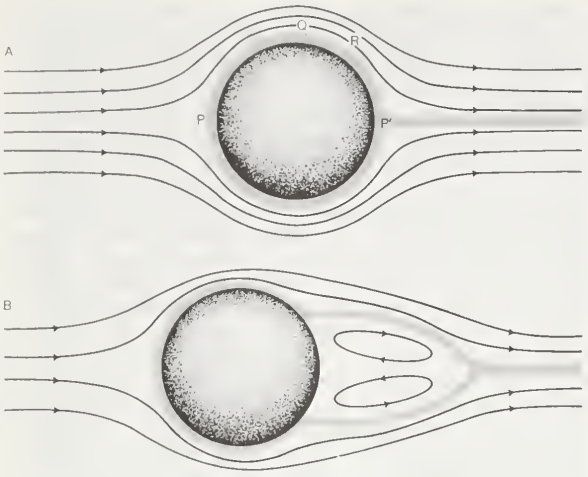

Figure 58: *Flow past a stationary solid sphere.*
The fluid is free of vorticity outside a boundary layer, which is represented by shading. In (A) the boundary layer is still attached to the sphere, though it continues downstream of it. In (B) it has separated, and an eddy has formed behind the sphere.

The diagrams in Figure 58 might well refer to a cylinder rather than a sphere. If such were the case, however, the regions of circulating flow behind the obstacle that are shown in the second diagram would form parts of two separate straight eddies instead of a single ring-shaped one. At high velocities the eddies behind a cylinder become so large that they are blown off by the current and disappear downstream while new eddies form in their place; they are said to have been shed. The top and bottom eddies are shed alternately, and the cylinder experiences an oscillating force as a consequence. If the cylinder is something flexible like a telephone or power cable, it will move to and fro under this force; the singing noise produced by cables in high winds is due to a resonance between their natural frequency of transverse oscillation and the frequency of eddy shedding. Similar processes are liable to occur behind obstacles of any shape, and the occurrence of eddies behind rocks or walls that interrupt the smooth flow of rivers is a familiar phenomenon.

Eddy shedding

DRAG

A fluid stream exerts a drag force F_D on any obstacle placed in its path, and the same force arises if the obstacle moves and the fluid is stationary. How large it is and how it may be reduced are questions of obvious importance to designers of moving vehicles of all sorts and equally to designers of cooling towers and other structures who want to be certain that the structures will not collapse in the face of winds.

An expression for the drag force on a sphere which is valid at such low velocities that the v^2 term in the Navier-Stokes equation is negligible, and thus at velocities such that the boundary layer thickness described by (171) is larger than the sphere diameter D, was first obtained by Stokes. Known as Stokes's law, it may be written as

Stokes's law

$$F_D = 3\pi\eta D v_0. \tag{172}$$

One-third of this force is transmitted to the sphere by shear stresses near the equator, and the remaining two-thirds are due to the pressure being higher at the front of the sphere than at the rear.

As the velocity increases and the boundary layer decreases in thickness, the effect of the shear stresses (or of what is sometimes called skin friction in this context) becomes less and less important compared with the effect of the pressure difference. It is impossible to calculate that difference precisely, except in the limit to which Stokes's law applies, but there are grounds for expecting that once eddies have formed it is about $\rho v_0^2/2$. Hence at high velocities one may expect

$$F_D = \left(\frac{\rho v_0^2}{2}\right) A', \tag{173}$$

where A' is some effective cross-sectional area, presumably comparable to its true cross-sectional area A (which is $\pi D^2/4$ for a sphere) but not necessarily exactly equal to this. It is conventional to describe drag forces in terms of a dimensionless quantity called the drag coefficient; this is defined, irrespective of the shape of the body, as the ratio $[F_D/(\rho v_0^2/2)A]$ and is denoted by C_D. At high velocities, C_D is clearly the same thing as the ratio (A'/A) and should therefore be of order unity.

This is as far as theory can go with this problem. The principles of dimensional analysis can be invoked to show that, provided the compressibility of the fluid is irrelevant (*i.e.*, provided the flow velocity is well below the speed of sound), the drag coefficient must be some universal function of another dimensionless quantity known as the Reynolds number and defined as

$$R = \frac{\rho v_0 D}{\eta}. \tag{174}$$

One must, however, resort to experiments to discover the form of this function. Fortunately, a limited number of experiments will suffice because the function is universal. They can be performed using whatever liquids and spheres are most convenient, provided that the whole range of R that is likely to be important is covered. Once the results have been plotted on a graph of C_D versus R, the graph can be used to predict the drag forces experienced by other spheres in other liquids at velocities that may be quite different from those so far employed. This point is worth emphasizing because it enshrines the principle of dynamic similarity, which is heavily relied on by engineers whenever they use results obtained with models to predict the behaviour of much larger structures.

The C_D versus R curve for spheres, plotted with logarithmic scales, is shown in Figure 59. Stokes's law, re-expressed in terms of C_D and R, becomes $C_D = 24/R$, and it is represented by the straight line on the left of the diagram. This law evidently fails when R exceeds about 1. There is a considerable range of R in the middle of the diagram over which C_D is about 0.5, but when R reaches about 3×10^{-5} it falls dramatically, to about 0.1. The figure includes the corresponding curves for cylinders of diameter D whose axes are transverse to the direction of flow and for transverse disks of diameter D. The curve for cylinders is similar to that for spheres (though it has no straight-line part at low Reynolds number to correspond to Stokes's law), but the curve for disks is noticeably flatter. This flatness is linked to the fact that a disk has sharp edges around which the streamlines converge and diverge rapidly. The resulting large pressure gradients near the edge favour the formation and shedding of eddies. The drag force on a transverse flat plate of any shape can normally be estimated quite accurately, provided its edges are sharp, by assuming the drag coefficient to be unity.

Since sharp edges favour the formation and shedding of eddies, and thereby increase the drag coefficient, one may hope to reduce the drag coefficient by streamlining the obstacle. It is at the rear of the obstacle that separation occurs, and it is therefore the rear that needs streamlining.

Reducing drag

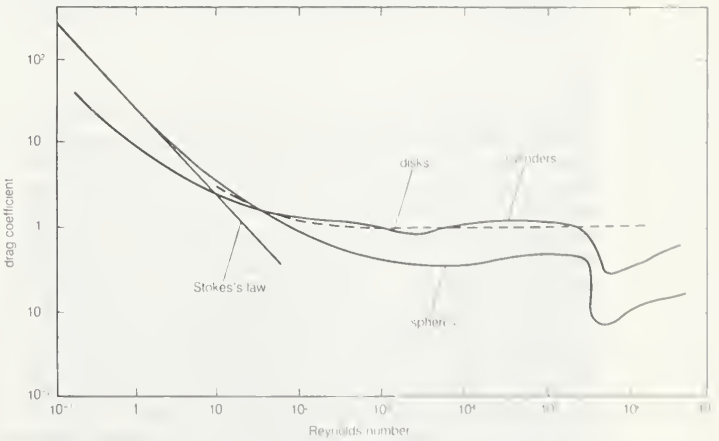

Figure 59: Variation of drag coefficient with Reynolds number for spheres, cylinders, and disks (see text).

By stretching this out in the manner suggested in Figure 60A, the pressure gradient acting on the boundary layer behind the obstacle can be much reduced. Other methods of reducing drag that have some practical applications are illustrated in Figures 60B and 60C. In 60B the obstacle is the wing of an aircraft with a slot through its leading edge; the current of air channeled through this slot imparts forward momentum to the fluid in the boundary layer on the upper surface of the wing to hinder this fluid from moving backward. The cowls that are often fitted to the leading edges of aircraft wings have a similar purpose. In Figure 60C, the obstacle is equipped with an internal device—a pump of some sort—which prevents the accumulation of boundary-layer fluid that would otherwise lead to separation by sucking it in through small holes in the surface of the obstacle, near Q; the fluid may be ejected again through holes near P′, where it will do no harm.

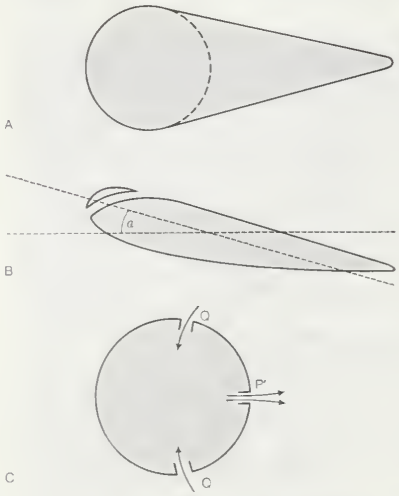

Figure 60: *Methods for reducing drag.*
Each diagram represents a solid object that is stationary in the path of a fluid flowing from left to right, or that is moving from right to left through a fluid which is stationary: (A) a sphere that has been streamlined; (B) an aircraft wing, inclined at angle α, which is slotted along its leading edge; (C) a sphere equipped with an internal pump, which draws fluid in near Q and expels it at P′.

It should be stressed that the curves in Figure 59 are universal only so long as the velocity v_0 is much less than the speed of sound. When v_0 is comparable with the speed of sound, V_S, the compressibility of the fluid becomes relevant, which means that the drag coefficient has to be regarded as dependent on the dimensionless ratio $M = v_0/V_S$, known as the Mach number, as well as on the Reynolds number. The drag coefficient always rises as M approaches unity but may thereafter fall. To reduce drag in the supersonic region, it pays to streamline the front of obstacles or projectiles rather than the rear, as this reduces the intensity of the shock cone (see above *Compressible flow in gases*).

LIFT

If an aircraft wing, or airfoil, is to fulfill its function, it must experience an upward lift force, as well as a drag force, when the aircraft is in motion. The lift force arises because the speed at which the displaced air moves over the top of the airfoil (and over the top of the attached boundary layer) is greater than the speed at which it moves over the bottom and because the pressure acting on the airfoil from below is therefore greater than the pressure from above. It also can be seen, however, as an inevitable consequence of the finite circulation that exists around the airfoil. One way to establish circulation around an obstacle is to rotate it, as was seen earlier in the description of the Magnus effect. The circulation around an airfoil, however, is created by its forward motion; it arises as soon as the airfoil moves fast enough to shed its first eddy.

The lift force on an airfoil moving through stationary air at a steady speed v_0 is the same as the lift force on an identical airfoil that is stationary in air moving at v_0 the other way; the latter is easier to represent pictorially. Figure 61A shows a set of streamlines representing potential flow past a stationary inclined plate before any eddy has been shed. The pattern is a symmetrical one, and the pressure variations associated with it generate neither drag nor lift. At the rear of the plate, however, the streamlines diverge rapidly, so conditions exist for the formation of an eddy there, and the sense of its rotation will be counterclockwise. It grows more easily and is shed more quickly because the edges of the plate are sharp. Figure 61B shows some streamlines for the same plate a moment after shedding when the detached eddy, known as the starting vortex, is still in view. The circulation around the closed loop shown by a broken curve in this diagram was zero before the eddy formed and, according to Thomson's theorem (see above), it must still be zero. Passing through this loop, there thus must be a vortex line having clockwise circulation $-K$ to compensate for the circulation $+K$ of the starting vortex. This other line, known as the bound vortex, is not immediately apparent in the diagram because it is attached to the plate, and it remains thus attached as the starting vortex is swept away downstream. It does show up, however, in a modification of the flow pattern immediately behind the plate, where the streamlines no longer diverge as they do in Figure 61A. Because the divergence here has been eliminated, no further eddies are likely to be formed.

Starting vortex and bound vortex

Earlier, the formula $\rho v_0 K$ was quoted for the strength of the Magnus force per unit length of a rotating cylinder, and the same formula can be applied to the inclined plate in Figure 61B or to any airfoil that has shed a starting vortex and around which, consequently, there is circulation. The validity of the formula does not depend in any way on the precise shape of the airfoil, any more than the force exerted by a magnetic field on a wire carrying a current depends on the cross-sectional shape of the wire. The design of the airfoil, nevertheless, has a critical effect on the magnitude of the lift force because it determines the magnitude of K. The sort of cross section that is adopted for the wings of aircraft has been sketched already in Figure 60B. The rear edge is made as sharp as possible for reasons that have already been explained, and it may take the form of hinged flaps that are lowered at takeoff. Lowering the flaps increases K and therefore also the lift, but the flaps need to be raised when the aircraft has reached its cruising altitude because they cause undesirable drag. The circulation and the lift can also be increased by increasing

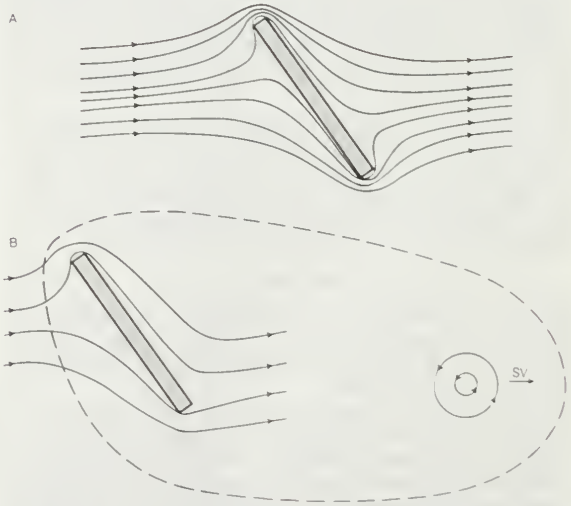

Figure 61: *Generation of lift force.*
(A) Streamlines for potential flow past a stationary inclined plate; conditions exist for formation of an eddy behind the plate, with counterclockwise rotation. (B) An eddy formed behind the plate in (A) has been shed as a starting vortex (SV), which is being carried downstream. The circulation remains zero around the large loop indicated by a broken line, and the streamlines no longer diverge behind the rear edge of the plate, as they do in (A) (see text).

the angle α (see Figure 60B) at which the main part of the airfoil is inclined to the direction of motion. There is a limit to the lift that can be generated in this way, however, for if the inclination is too great the boundary layer separates behind the wing's leading edge, and the bound vortex, on which the lift depends, may be shed as a result. The aircraft is then said to stall. The leading edge is made as smooth and rounded as possible to discourage stalling.

Thomson's theorem can be used to prove that if the airfoil is of finite length then the starting vortex and the bound vortex must both be parts of a single, continuous vortex ring. They are joined by two trailing vortices, which run backward from the ends of the airfoil. As time passes, these trailing vortices grow steadily longer, and more and more energy is needed to feed the swirling motion of the fluid around them. It is clear, at any rate in the case where the airfoil is moving and the air is stationary, that this energy can come only from whatever agency propels the airfoil forward, and hence that the trailing vortices are a source of additional drag. The magnitude of the additional drag is proportional to K^2 but it does not increase, as the lift force does, if the airfoil is made longer while K is kept the same. For this reason, designers who wish to maximize the ratio of lift to drag will make the wings of their aircraft as long as they can—as long, that is, as is consistent with strength and rigidity requirements.

Trailing vortices

When a yacht is sailing into the wind, its sail acts as an airfoil of which the mast is the leading edge, and the considerations that favour long wings for aircraft favour tall masts as well.

TURBULENCE

The nonlinear nature of the $(\boldsymbol{v} \cdot \nabla)\boldsymbol{v}$ term in the Navier-Stokes equation—equation (155)—means that solutions of this equation cannot be superposed. The fact that $\boldsymbol{v}_1(\boldsymbol{R}, t)$ and $\boldsymbol{v}_2(\boldsymbol{R}, t)$ satisfy the equation does not ensure that $(\boldsymbol{v}_1 + \boldsymbol{v}_2)$ does so too. The nonlinear term provides a contact, in fact, through which two different modes of motion may exchange energy, so that one grows in amplitude at the expense of the other. A great deal of experimental and theoretical work has shown, in particular, that if a fluid is undergoing regular laminar motion (of the sort that was discussed in connection with Poiseuille's law, for example) at sufficiently high rates of shear, small periodic perturbations of this motion are liable to grow parasitically. Perturbations on a smaller scale still grow parasitically on those that are first established, until the flow pattern is so grossly disturbed that it is no longer useful to define a fluid velocity for each point in space; the description of the flow has to be a statistical one in terms of mean values and of correlated fluctuations about the mean. The flow is then said to be turbulent.

Turbulent flow

In the case (to which Poiseuille's law applies) of laminar flow through a uniform cylindrical pipe of diameter D, turbulence inevitably sets in when the Reynolds number R reaches a critical value that is about 10^5; in this context, the Reynolds number is defined (compare equation [174]) as

$$R = \frac{4\rho Q}{\pi D \eta} = \frac{\rho D \langle v \rangle}{\eta}, \qquad (175)$$

where Q is the rate of discharge and $\langle v \rangle$ is the mean fluid velocity. Turbulence sets in at much lower velocities, however, if the end of the pipe where the fluid enters is not carefully flared. The critical value of the Reynolds number for a pipe with a bluff entry may be as low as 2300, and this corresponds to a rate of discharge through a pipe for which D is, say, two centimetres, of only about three litres per minute. Thus pipe flow in engineering practice is more often turbulent than not. Once turbulence has set in, Q increases less rapidly with pressure gradient than Poiseuille's equation—equation (150)—predicts; it increases roughly as the square root of the pressure gradient or slightly more rapidly than this if the internal surface of the pipe is very smooth.

Turbulence within boundary layers

Turbulence arises not only in pipes but also within boundary layers around solid obstacles when the rate of shear within the boundary layer becomes large enough. Curiously enough, the onset of turbulence in the boundary layer can reduce the drag force on obstacles. In the case of a spherical obstacle, the point at which the boundary layer separates from the rear surface of the sphere shifts backward when the boundary layer becomes turbulent, away from the equator Q in Figure 58 and toward P′, and the eddies attached to the sphere therefore become smaller. It is turbulence in the boundary layer that is responsible for the dramatic drop in the drag coefficient for both spheres and cylinders that occurs, as can be seen from Figure 59, when the Reynolds number is about 3×10^5. This drop enables golf balls to travel farther than they would do otherwise, and the dimples on the surface of golf balls are meant to encourage turbulence in the boundary layer. If swimsuits with rough surfaces help swimmers to move faster, as has been claimed, the same explanation may apply.

Where conditions for turbulence exist, flow rates of water through tubes may be increased and the drag forces exerted on obstacles by water diminished by dissolving small amounts of suitable polymers in the water. This is surprising, because such additives increase viscosity, and in the preturbulent regime to which Poiseuille's law applies, their effect on the flow rate is quite the reverse. As has already been stated, the small perturbations that arise in a turbulent fluid tend to collapse into smaller perturbations and then into smaller perturbations still, until the motion is turbulent on a very fine scale—*i.e.*, on the scale of molecular dimensions—and until the energy stored in the perturbations is finally dissipated as heat. Polymer molecules seem to have the effect they do because, over the relatively large distances to which each such molecule extends, they impose a coherence on the fluid motion that would not otherwise be present.

Effect of polymer additives

CONVECTION

Apart from some remarks in the above section *Compressible flow in gases* about the circulation of the atmosphere, no attention has yet been paid to situations in which temperature differences are imposed upon a fluid by contact with hot and cold bodies. This subject will be briefly taken up here.

Consider first the case of two vertical plates with fluid between them, one at temperature T_1 and the other at T_2, in the presence of a vertical gravitational field. The hotter plate might be a domestic radiator and the colder plate the wall to which it is fixed. Thermal conduction ensures that the layer of air adjacent to the radiator is hotter than the rest of the air, and thermal expansion ensures that it is less dense. Consequently, the vertical pressure gradient which satisfies equation (123) in the rest of the air is too large to keep the layer adjacent to the radiator in equilibrium; that layer rises and, similarly, the cold layer adjacent to the wall falls. A circulating pattern of thermal convection is thereby established, and, because this brings colder air into contact with the radiator, the rate at which heat is lost from the radiator is enhanced. The heat loss, once convection has been established, depends in a complicated manner on the separation between the plates (D) and on the thermal diffusivity (κ), specific heat, density, thermal expansion coefficient (α), and viscosity of the fluid. The heat loss also depends on $(T_1 - T_2)$, of course, and it is worthwhile noting that the manner in which it does so is not linear; the heat loss increases more rapidly than the temperature difference. Newton's law of cooling, which postulates a linear relationship, is obeyed only in circumstances where convection is prevented or in circumstances where it is forced (when a radiator is fan-assisted, for example).

Imagine a situation in which the same two plates are horizontal rather than vertical. In such a case, no convection can occur if the hot plate is above the cold one, and it is not obvious that it occurs in the reverse situation. Whether it does so or not depends on the magnitude of the temperature difference through a dimensionless combination of some of the relevant parameters, $\rho g \alpha D^3 (T_1 - T_2)/\eta\kappa$, which is known as the Rayleigh number. If the Rayleigh number is less than 1,708, the fluid is stable—or perhaps it would be more accurate to say that it is metastable—even though it is warmer at the bottom than at the top. How-

Bénard cells

ever, when 1,708 is exceeded, a pattern of convective rolls known as Bénard cells is established between the plates. Evidence for the existence of such cells in the convecting atmosphere is sometimes seen in the regular columns of cloud that form over regions where the air is rising. Their periodicity can be astonishingly uniform.

Macroscopic instabilities of a convective nature, of which the formation of Bénard cells provides just one example, are a feature of the oceans as well as of the atmosphere and are frequently associated with gradients of salinity rather than gradients of temperature. A serious discussion of atmospheric and oceanic circulation on the Earth, however, requires a more detailed examination of the dynamics of rotating fluids than is given here. (T.E.F.)

QUANTUM MECHANICS

Quantum mechanics deals with the behaviour of matter and light on the atomic and subatomic scale. It attempts to describe and account for the properties of molecules and atoms and their constituents—electrons, protons, neutrons, and other more esoteric particles such as quarks and gluons. These properties include the interactions of the particles with one another and with electromagnetic radiation (*i.e.*, light, X rays, and gamma rays).

The behaviour of matter and radiation on the atomic scale often seems peculiar, and the consequences of quantum theory are accordingly difficult to understand and to believe. Its concepts frequently conflict with commonsense notions derived from observations of the everyday world. There is no reason, however, why the behaviour of the atomic world should conform to that of the familiar, large-scale world. It is important to realize that quantum mechanics is a branch of physics and that the business of physics is to describe and account for the way the world—on both the large and the small scale—actually is and not how one imagines it or would like it to be.

The study of quantum mechanics is rewarding for several reasons. First, it illustrates the essential methodology of physics. Second, it has been enormously successful in giving correct results in practically every situation to which it has been applied. There is, however, an intriguing paradox. In spite of the overwhelming practical success of quantum mechanics, the foundations of the subject contain unresolved problems—in particular, problems concerning the nature of measurement. An essential feature of quantum mechanics is that it is generally impossible, even in principle, to measure a system without disturbing it; the detailed nature of this disturbance and the exact point at which it occurs are obscure and controversial. Thus, quantum mechanics has attracted some of the ablest scientists of the 20th century, and they have erected what is perhaps the finest intellectual edifice of the period.

Historical basis of quantum theory

BASIC CONSIDERATIONS

At a fundamental level, both radiation and matter have characteristics of particles and waves. The gradual recognition by scientists that radiation has particle-like properties and that matter has wavelike properties provided the impetus for the development of quantum mechanics. Influenced by Newton, most physicists of the 18th century believed that light consisted of particles, which they called corpuscles. From about 1800, evidence began to accumulate for a wave theory of light. At about this time Thomas Young showed that, if monochromatic light passes through a pair of slits, the two emerging beams interfere, so that a fringe pattern of alternately bright and dark bands appears on a screen. The bands are readily explained by a wave theory of light. According to the theory, a bright band is produced when the crests (or troughs) of the waves from the two slits arrive together at the screen; a dark band is produced when the crest of one wave arrives at the same time as the trough of the other, and the effects of the two light beams cancel. Beginning in 1815, a series of experiments by Augustin-Jean Fresnel of France and others showed that, when a parallel beam of light passes through a single slit, the emerging beam is no longer parallel but starts to diverge; this phenomenon is known as diffraction. Given the wavelength of the light and the geometry of the apparatus (*i.e.*, the separation and widths of the slits and the distance from the slits to the screen), one can use the wave theory to calculate the expected pattern in each case; the theory agrees precisely with the experimental data.

Support for a wave theory of light

EARLY DEVELOPMENTS

Planck's radiation law. By the end of the 19th century, physicists almost universally accepted the wave theory of light. However, though the ideas of classical physics explain interference and diffraction phenomena relating to the propagation of light, they do not account for the absorption and emission of light. All bodies radiate electromagnetic energy as heat; in fact, a body emits radiation at all wavelengths. The energy radiated at different wavelengths is a maximum at a wavelength that depends on the temperature of the body; the hotter the body, the shorter the wavelength for maximum radiation. Attempts to calculate the energy distribution for the radiation from a blackbody using classical ideas were unsuccessful. (A blackbody is a hypothetical ideal body or surface that absorbs and reemits all radiant energy falling on it.) One formula, proposed by Wilhelm Wien of Germany, did not agree with observations at long wavelengths, and another, proposed by Lord Rayleigh (John William Strutt) of England, disagreed with those at short wavelengths.

In 1900 the German theoretical physicist Max Planck made a bold suggestion. He assumed that the radiation energy is emitted, not continuously, but rather in discrete packets called quanta. The energy E of the quantum is related to the frequency ν by

Concept of quantum

$$E = h\nu. \tag{176}$$

The quantity h, now known as the Planck constant, is a universal constant with the approximate value $h = 6.63 \times 10^{-34}$ joule-second. (The more precise, currently accepted value is 6.626075×10^{-34} joule-second.) Planck showed that the calculated energy spectrum then agreed with observation over the entire wavelength range.

Einstein and the photoelectric effect. In 1905 Einstein extended Planck's hypothesis to explain the photoelectric effect, which is the emission of electrons by a metal surface when it is irradiated by light or X rays. The kinetic energy of the emitted electrons depends on the frequency ν of the radiation, not on its intensity; for a given metal, there is a threshold frequency ν_0 below which no electrons are emitted. Furthermore, emission takes place as soon as the light shines on the surface; there is no detectable delay. Einstein showed that these results can be explained by two assumptions: (1) that light is composed of corpuscles or photons, the energy of which is given by Planck's relationship, and (2) that an atom in the metal can absorb either a whole photon or nothing. Part of the energy of the absorbed photon frees an electron, which requires a fixed energy W, known as the work function of the metal; the rest is converted into the kinetic energy $\frac{1}{2}m_e u^2$ of the emitted electron (m_e is the mass of the electron and u is its velocity). Thus, the energy relation is

$$h\nu = W + \frac{1}{2}m_e u^2. \tag{177}$$

If ν is less than ν_0, where $h\nu_0 = W$, no electrons are emitted. Not all the experimental results mentioned above were known in 1905, but all Einstein's predictions have been verified since.

Bohr's theory of the atom. A major contribution to the subject was made by Niels Bohr of Denmark, who applied the quantum hypothesis to atomic spectra in 1913. The spectra of light emitted by gaseous atoms had been studied extensively since the mid-19th century. It was found that

radiation from gaseous atoms at low pressure consists of a set of discrete wavelengths. This is quite unlike the radiation from a solid, which is distributed over a continuous range of wavelengths. The set of discrete wavelengths from gaseous atoms is known as a line spectrum, because the image of the linear slit in the spectrometer is a series of sharp lines. The wavelengths of the lines are characteristic of the element and may form extremely complex patterns. The simplest spectra are those of atomic hydrogen and the alkali atoms (*e.g.*, lithium, sodium, and potassium). For hydrogen, the wavelengths λ are given by the empirical formula

Line spectrum

$$\frac{1}{\lambda} = R_\infty\left(\frac{1}{m^2} - \frac{1}{n^2}\right), \tag{178}$$

where m and n are positive integers with $n > m$ and R_∞ known as the Rydberg constant, has the value 1.0973731×10^7 per metre. For a given value of m, the lines for varying n form a series. The lines for $m = 1$, the Lyman series, lie in the ultraviolet part of the spectrum. Those for $m = 2$, the Balmer series, lie in the visible spectrum, and so on.

Bohr started with a model suggested by the New Zealand-born British physicist Ernest Rutherford. The model was based on the experiments of Hans Geiger and Ernest Marsden, who in 1909 bombarded gold atoms with massive, fast-moving alpha particles; when some of these particles were deflected backward, Rutherford concluded that the atom has a massive, charged nucleus. In Rutherford's model, the atom resembles a miniature solar system with the nucleus acting as the Sun and the electrons as the circulating planets. Bohr made three assumptions. First, he postulated that, in contrast to classical mechanics, where an infinite number of orbits is possible, an electron can be in only one of a discrete set of orbits, which he termed stationary states. Second, he postulated that the only orbits allowed are those for which the angular momentum of the electron is a whole number n times $\hbar$ ($\hbar$ stands for $h/2\pi$). Third, Bohr assumed that Newton's laws of motion, so successful in calculating the paths of the planets around the Sun, also applied to electrons orbiting the nucleus. The force on the electron (the analogue of the gravitational force between the Sun and a planet) is the electrostatic attraction between the positively charged nucleus and the negatively charged electron. With these simple assumptions, he showed that the energy of the orbit has the form

$$E_n = -\frac{E_0}{n^2}, \tag{179}$$

where E_0 is a constant that may be expressed by a combination of the known constants e, m_e, and $\hbar$. While in a stationary state, the atom does not give off energy as light; however, when an electron makes a transition from a state with energy E_n to one with lower energy E_m, a quantum of energy is radiated with frequency ν, given by the equation

$$h\nu = E_n - E_m. \tag{180}$$

Inserting the expression for E_n into this equation and using the relation $\lambda\nu = c$, where c is the speed of light, Bohr derived the formula for the wavelengths of the lines in the hydrogen spectrum, with the correct value of the Rydberg constant.

Most important features of Bohr's theory

Bohr's theory was a brilliant step forward. Its two most important features have survived in present-day quantum mechanics. They are (1) the existence of stationary, nonradiating states and (2) the relationship of radiation frequency to the energy difference between the initial and final states in a transition. Prior to Bohr, physicists had thought that the radiation frequency would be the same as the electron's frequency of rotation in an orbit.

Scattering of X rays. Soon scientists were faced with the fact that another form of radiation, X rays, also exhibits both wave and particle properties. Max von Laue of Germany had shown in 1912 that crystals can be used as three-dimensional diffraction gratings for X rays; his technique constituted the fundamental evidence for the wavelike nature of X rays. The atoms of a crystal, which are arranged in a regular lattice, scatter the X rays. For certain directions of scattering, all the crests of the X rays coincide. (The scattered X rays are said to be in phase and to give constructive interference.) For these directions, the scattered X-ray beam is very intense. Clearly, this phenomenon demonstrates wave behaviour. In fact, given the interatomic distances in the crystal and the directions of constructive interference, the wavelength of the waves can be calculated.

In 1922 the American physicist Arthur Holly Compton showed that X rays scatter from electrons as if they are particles. Compton performed a series of experiments on the scattering of monochromatic, high-energy X rays by graphite. He found that part of the scattered radiation had the same wavelength λ_0 as the incident X rays but that there was an additional component with a longer wavelength λ. To interpret his results, Compton regarded the X-ray photon as a particle that collides and bounces off an electron in the graphite target as though the photon and the electron were a pair of (dissimilar) billiard balls. Application of the laws of conservation of energy and momentum to the collision leads to a specific relation between the amount of energy transferred to the electron and the angle of scattering. For X rays scattered through an angle θ, the wavelengths λ and λ_0 are related by the equation

$$\lambda - \lambda_0 = \frac{h}{m_e c}(1 - \cos\theta). \tag{181}$$

The experimental correctness of Compton's formula is direct evidence for the corpuscular behaviour of radiation.

Broglie's wave hypothesis. Faced with evidence that electromagnetic radiation has both particle and wave characteristics, Louis-Victor de Broglie of France suggested a great unifying hypothesis in 1924. Broglie proposed that matter has wave, as well as particle, properties. He suggested that material particles can behave as waves and that their wavelength λ is related to the linear momentum p of the particle by

Wave-particle hypothesis

$$\lambda = \frac{h}{p}. \tag{182}$$

In 1927 Clinton Davisson and Lester Germer of the United States confirmed Broglie's hypothesis for electrons. Using a crystal of nickel, they diffracted a beam of monoenergetic electrons and showed that the wavelength of the waves is related to the momentum of the electrons by the Broglie equation. Since Davisson and Germer's investigation, similar experiments have been performed with atoms, molecules, neutrons, protons, and many other particles. All behave like waves with the same wavelength-momentum relationship.

Basic concepts and methods

Bohr's theory, which assumed that electrons moved in circular orbits, was extended by the German physicist Arnold Sommerfeld and others to include elliptic orbits and other refinements. Attempts were made to apply the theory to more complicated systems than the hydrogen atom. However, the ad hoc mixture of classical and quantum ideas made the theory and calculations increasingly unsatisfactory. Then in the 12 months starting in July 1925, a period of creativity without parallel in the history of physics, there appeared a series of papers by German scientists that set the subject on a firm conceptual foundation. The papers took two approaches: (1) matrix mechanics, proposed by Werner Heisenberg, Max Born, and Pascual Jordan, and (2) wave mechanics, put forward by Erwin Schrödinger. The protagonists were not always polite to each other. Heisenberg found the physical ideas of Schrödinger's theory "disgusting," and Schrödinger was "discouraged and repelled" by the lack of visualization in Heisenberg's method. However, Schrödinger, not allowing his emotions to interfere with his scientific endeavours, showed that, in spite of apparent dissimilarities, the two theories are equivalent mathematically. The present discussion follows Schrödinger's wave mechanics because it is less abstract and easier to understand than Heisenberg's matrix mechanics.

SCHRÖDINGER'S WAVE MECHANICS

Schrödinger expressed Broglie's hypothesis concerning the wave behaviour of matter in a mathematical form that is adaptable to a variety of physical problems without additional arbitrary assumptions. He was guided by a mathematical formulation of optics, in which the straight-line propagation of light rays can be derived from wave motion when the wavelength is small compared to the dimensions of the apparatus employed. In the same way, Schrödinger set out to find a wave equation for matter that would give particle-like propagation when the wavelength becomes comparatively small. According to classical mechanics, if a particle of mass m_e is subjected to a force such that its potential energy is $V(x,y,z)$ at position x,y,z, then the sum of $V(x,y,z)$ and the kinetic energy $p^2/2m_e$ is equal to a constant, the total energy E of the particle. Thus,

$$\frac{p^2}{2m_e} + V(x,y,z) = E. \qquad (183)$$

It is assumed that the particle is bound—*i.e.*, confined by the potential to a certain region in space because its energy E is insufficient for it to escape. Since the potential varies with position, two other quantities do also: the momentum and, hence, by extension from the Broglie relation, the wavelength of the wave. Postulating a wave function $\Psi(x,y,z)$ that varies with position, Schrödinger replaced p in the above energy equation with a differential operator that embodied the Broglie relation. He then showed that Ψ satisfies the partial differential equation

$$-\frac{\hbar^2}{2m_e}\left(\frac{\partial^2\Psi}{\partial x^2} + \frac{\partial^2\Psi}{\partial y^2} + \frac{\partial^2\Psi}{\partial z^2}\right) + V(x,y,z)\Psi = E\Psi. \qquad (184)$$

Time-independent Schrödinger wave equation

This is the (time-independent) Schrödinger wave equation of 1926, which established quantum mechanics in a widely applicable form. An important advantage of Schrödinger's theory is that no further arbitrary quantum conditions need be postulated. The required quantum results follow from certain reasonable restrictions placed on the wave function—for example, that it should not become infinitely large at large distances from the centre of the potential.

Schrödinger applied his equation to the hydrogen atom, for which the potential function, given by classical electrostatics, is proportional to $-e^2/r$, where $-e$ is the charge on the electron. The nucleus (a proton of charge e) is situated at the origin, and r is the distance from the origin to the position of the electron. Schrödinger solved the equation for this particular potential with straightforward, though not elementary, mathematics. Only certain discrete values of E lead to acceptable functions Ψ. These functions are characterized by a trio of integers n, l, m, termed quantum numbers. The values of E depend only on the integers n (1, 2, 3, etc.) and are identical with those given by the Bohr theory. The quantum numbers l and m are related to the angular momentum of the electron; $\sqrt{l(l+1)}\hbar$ is the magnitude of the angular momentum, and $m\hbar$ is its component along some physical direction.

The square of the wave function, Ψ^2, has a physical interpretation. Schrödinger originally supposed that the electron was spread out in space and that its density at point x,y,z was given by the value of Ψ^2 at that point. Almost immediately Born proposed what is now the accepted interpretation—namely, that Ψ^2 gives the probability of finding the electron at x,y,z. The distinction between the two interpretations is important. If Ψ^2 is small at a particular position, the original interpretation implies that a small fraction of an electron will always be detected there. In Born's interpretation, nothing will be detected there most of the time, but, when something is observed, it will be a whole electron. Thus, the concept of the electron as a point particle moving in a well-defined path around the nucleus is replaced in wave mechanics by clouds that describe the probable locations of electrons in different states.

ELECTRON SPIN AND ANTIPARTICLES

In 1928 the English physicist Paul A.M. Dirac produced a wave equation for the electron that combined relativity with quantum mechanics. Schrödinger's wave equation does not satisfy the requirements of the special theory of relativity because it is based on a nonrelativistic expression for the kinetic energy ($p^2/2m_e$). Dirac showed that an electron has an additional quantum number m_s. Unlike the first three quantum numbers, m_s is not a whole integer and can have only the values $+\frac{1}{2}$ and $-\frac{1}{2}$. It corresponds to an additional form of angular momentum ascribed to a spinning motion. (The angular momentum mentioned above is due to the orbital motion of the electron, not its spin.) The concept of spin angular momentum was introduced in 1925 by Samuel A. Goudsmit and George E. Uhlenbeck, two graduate students at the University of Leiden, Neth., to explain the magnetic moment measurements made by Otto Stern and Walther Gerlach of Germany several years earlier. The magnetic moment of a particle is closely related to its angular momentum; if the angular momentum is zero, so is the magnetic moment. Yet Stern and Gerlach had observed a magnetic moment for electrons in silver atoms, which were known to have zero orbital angular momentum. Goudsmit and Uhlenbeck proposed that the observed magnetic moment was attributable to spin angular momentum.

Dirac's relativistic wave equation

The electron-spin hypothesis not only provided an explanation for the observed magnetic moment but also accounted for many other effects in atomic spectroscopy, including changes in spectral lines in the presence of a magnetic field (Zeeman effect), doublet lines in alkali spectra, and fine structure (close doublets and triplets) in the hydrogen spectrum.

The Dirac equation also predicted additional states of the electron that had not yet been observed. Experimental confirmation was provided in 1932 by the discovery of the positron by the American physicist Carl David Anderson. Every particle described by the Dirac equation has to have a corresponding antiparticle, which differs only in charge. The positron is just such an antiparticle of the negatively charged electron, having the same mass as the latter but a positive charge.

IDENTICAL PARTICLES AND MULTIELECTRON ATOMS

Because electrons are identical to (*i.e.*, indistinguishable from) each other, the wave function of an atom with more than one electron must satisfy special conditions. The problem of identical particles does not arise in classical physics, where the objects are large-scale and can always be distinguished, at least in principle. There is no way, however, to differentiate two electrons in the same atom, and the form of the wave function must reflect this fact. The overall wave function Ψ of a system of identical particles depends on the coordinates of all the particles. If the coordinates of two of the particles are interchanged, the wave function must remain unaltered or, at most, undergo a change of sign; the change of sign is permitted because it is Ψ^2 that occurs in the physical interpretation of the wave function. If the sign of Ψ remains unchanged, the wave function is said to be symmetric with respect to interchange; if the sign changes, the function is antisymmetric.

The symmetry of the wave function for identical particles is closely related to the spin of the particles. In quantum field theory (see below *Quantum electrodynamics*), it can be shown that particles with half-integral spin ($\frac{1}{2}$, $\frac{3}{2}$, etc.) have antisymmetric wave functions. They are called fermions after the Italian-born physicist Enrico Fermi. Examples of fermions are electrons, protons, and neutrons, all of which have spin $\frac{1}{2}$. Particles with zero or integral spin (*e.g.*, mesons, photons) have symmetric wave functions and are called bosons after the Indian mathematician and physicist Satyendra Nath Bose, who first applied the ideas of symmetry to photons in 1924–25.

The requirement of antisymmetric wave functions for fermions leads to a fundamental result, known as the exclusion principle, first proposed in 1925 by the Austrian physicist Wolfgang Pauli. The exclusion principle states that two fermions in the same system cannot be in the same quantum state. If they were, interchanging the two sets of coordinates would not change the wave function at all, which contradicts the result that the wave function must change sign. Thus, two electrons in the same atom cannot have an identical set of values for the four quan-

Exclusion principle

tum numbers n, l, m, m_s. The exclusion principle forms the basis of many properties of matter, including the periodic classification of the elements, the nature of chemical bonds, and the behaviour of electrons in solids; the last determines in turn whether a solid is a metal, insulator, or semiconductor (see ATOMS; MATTER).

The Schrödinger equation cannot be solved precisely for atoms with more than one electron. The principles of the calculation are well understood, but the problems are complicated by the number of particles and the variety of forces involved. The forces include the electrostatic forces between the nucleus and the electrons and between the electrons themselves, as well as weaker magnetic forces arising from the spin and orbital motions of the electrons. Despite these difficulties, approximation methods introduced by the English physicist Douglas R. Hartree and others in the 1920s have achieved considerable success. Such schemes start by assuming that each electron moves independently in an average electric field because of the nucleus and the other electrons—*i.e.*, correlations between the positions of the electrons are ignored. Each electron has its own wave function, called an orbital. The overall wave function for all the electrons in the atom satisfies the exclusion principle. Corrections to the calculated energies are then made, which depend on the strengths of the electron-electron correlations and the magnetic forces.

Hartree method

TIME-DEPENDENT SCHRÖDINGER EQUATION

At the same time that Schrödinger proposed his time-independent equation to describe the stationary states, he also proposed a time-dependent equation to describe how a system changes from one state to another. By replacing the energy E in equation (184) with a time-derivative operator, he generalized his wave equation to determine the time variation of the wave function as well as its spatial variation. The time-dependent Schrödinger equation reads

$$-\frac{\hbar^2}{2m_e}\left(\frac{\partial^2\Psi}{\partial x^2}+\frac{\partial^2\Psi}{\partial y^2}+\frac{\partial^2\Psi}{\partial z^2}\right)+V(x,y,z)\Psi=i\hbar\frac{\partial\Psi}{\partial t}. \qquad (185)$$

The quantity i is the square root of -1. The function Ψ varies with time t as well as with position x,y,z. For a system with constant energy, E, Ψ has the form

$$\Psi(x,y,z,t)=\Psi(x,y,z)\exp\left(-\frac{iEt}{\hbar}\right), \qquad (186)$$

where exp stands for the exponential function, and the time-dependent Schrödinger equation reduces to the time-independent form.

The probability of a transition between one atomic stationary state and some other state can be calculated with the aid of the time-dependent equation. For example, an atom may change spontaneously from one state to another state with less energy, emitting the difference in energy as a photon with a frequency given by the Bohr relation. If electromagnetic radiation is applied to a set of atoms and if the frequency of the radiation matches the energy difference between two stationary states, transitions can be stimulated. In a stimulated transition, the energy of the atom may increase—*i.e.*, the atom may absorb a photon from the radiation—or the energy of the atom may decrease, with the emission of a photon, which adds to the energy of the radiation. Such stimulated emission processes form the basic mechanism for the operation of lasers. The probability of a transition from one state to another depends on the values of the l, m, m_s quantum numbers of the initial and final states. For most values, the transition probability is effectively zero. However, for certain changes in the quantum numbers, summarized as selection rules, there is a finite probability. For example, according to one important selection rule, the l value changes by unity. The selection rules for radiation relate to the angular momentum properties of the stationary states. The absorbed or emitted photon has its own angular momentum, and the selection rules reflect the conservation of angular momentum between the atoms and the radiation.

Transitions between atomic states

TUNNELING

The phenomenon of tunneling, which has no counterpart in classical physics, is an important consequence of quantum mechanics. Consider a particle with energy E in the inner region of a one-dimensional potential well $V(x)$, as shown in Figure 62. (A potential well is a potential that has a lower value in a certain region of space than in the neighbouring regions.) In classical mechanics, if $E < V_0$ (the maximum height of the potential barrier), the particle remains in the well forever; if $E > V_0$, the particle escapes. In quantum mechanics, the situation is not so simple. The particle can escape even if its energy E is below the height of the barrier V_0, although the probability of escape is small unless E is close to V_0. In that case, the particle may tunnel through the potential barrier and emerge with the same energy E.

No counterpart in classical physics

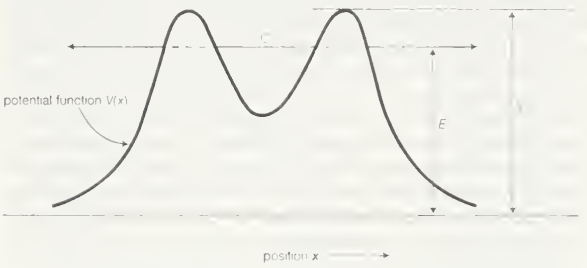

Figure 62: *The phenomenon of tunneling.* Classically, a particle is bound in the central region C if its energy E is less than V_0, but in quantum theory the particle may tunnel through the potential barrier and escape.

The phenomenon of tunneling has many important applications. For example, it describes a type of radioactive decay in which a nucleus emits an alpha particle (a helium nucleus). According to the quantum explanation given independently by George Gamow and by Ronald W. Gurney and Edward Condon in 1928, the alpha particle is confined before the decay by a potential of the shape shown in Figure 62. For a given nuclear species, it is possible to measure the energy E of the emitted alpha particle and the average lifetime τ of the nucleus before decay. The lifetime of the nucleus is a measure of the probability of tunneling through the barrier—the shorter the lifetime, the higher the probability. With plausible assumptions about the general form of the potential function, it is possible to calculate a relationship between τ and E that is applicable to all alpha emitters. This theory, which is borne out by experiment, shows that the probability of tunneling, and hence the value of τ, is extremely sensitive to the value of E. For all known alpha-particle emitters, the value of E varies from about 2 to 8 megaelectron volts, or MeV (1 MeV = 10^6 electron volts). Thus, the value of E varies only by a factor of 4, whereas the range of τ is from about 10^{11} years down to about 10^{-6} second, a factor of 10^{24}. It would be difficult to account for this sensitivity of τ to the value of E by any theory other than quantum mechanical tunneling.

AXIOMATIC APPROACH

Although the two Schrödinger equations form an important part of quantum mechanics, it is possible to present the subject in a more general way. Dirac gave an elegant exposition of an axiomatic approach based on observables and states in a classic textbook entitled *The Principles of Quantum Mechanics*. (The book, published in 1930, is still in print.) An observable is anything that can be measured—energy, position, a component of angular momentum, and so forth. Every observable has a set of states, each state being represented by an algebraic function. With each state is associated a number that gives the result of a measurement of the observable. Consider an observable with N states, denoted by $\varphi_1, \varphi_2, \ldots, \varphi_N$, and corresponding measurement values $a_1, a_2, \ldots, a_N$. A physical system—*e.g.*, an atom in a particular state—is represented by a wave function Ψ, which can be expressed as a linear combination, or mixture, of the states of the observable. Thus, the Ψ may be written as

Axiomatic approach based on observables and states

$$\Psi = c_1\varphi_1 + c_2\varphi_2 + \ldots + c_N\varphi_N. \qquad (187)$$

For a given Ψ, the quantities c_1, c_2, etc., are a set of numbers that can be calculated. In general, the numbers are

complex, but, in the present discussion, they are assumed to be real numbers.

The theory postulates, first, that the result of a measurement must be an a-value—*i.e.*, a_1, a_2, or a_3, etc. No other value is possible. Second, before the measurement is made, the probability of obtaining the value a_1 is c_1^2, and that of obtaining the value a_2 is c_2^2, and so on. If the value obtained is, say, a_5, the theory asserts that after the measurement the state of the system is no longer the original Ψ but has changed to φ_5, the state corresponding to a_5.

A number of consequences follow from these assertions. First, the result of a measurement cannot be predicted with certainty. Only the probability of a particular result can be predicted, even though the initial state (represented by the function Ψ) is known exactly. Second, identical measurements made on a large number of identical systems, all in the identical state Ψ, will produce different values for the measurements. This is, of course, quite contrary to classical physics and common sense, which say that the same measurement on the same object in the same state must produce the same result. Moreover, according to the theory, not only does the act of measurement change the state of the system, but it does so in an indeterminate way. Sometimes it changes the state to φ_1, sometimes to φ_2, and so forth.

There is an important exception to the above statements. Suppose that, before the measurement is made, the state Ψ happens to be one of the φs, say $\Psi = \varphi_3$. Then $c_3 = 1$ and all the other c's are zero. This means that, before the measurement is made, the probability of obtaining the value a_3 is unity and the probability of obtaining any other value of a is zero. In other words, in this particular case, the result of the measurement can be predicted with certainty. Moreover, after the measurement is made, the state will be φ_3, the same as it was before. Thus, in this particular case, measurement does not disturb the system. Whatever the initial state of the system, two measurements made in rapid succession (so that the change in the wave function given by the time-dependent Schrödinger equation is negligible) produce the same result.

The value of one observable can be determined by a single measurement. The value of two observables for a given system may be known at the same time, provided that the two observables have the same set of state functions $\varphi_1, \varphi_2, \ldots, \varphi_N$. In this case, measuring the first observable results in a state function that is one of the φs. Because this is also a state function of the second observable, the result of measuring the latter can be predicted with certainty. Thus the values of both observables are known. (Although the φs are the same for the two observables, the two sets of a values are, in general, different.) The two observables can be measured repeatedly in any sequence. After the first measurement, none of the measurements disturbs the system, and a unique pair of values for the two observables is obtained.

INCOMPATIBLE OBSERVABLES

Observables with different sets of state functions

The measurement of two observables with different sets of state functions is a quite different situation. Measurement of one observable gives a certain result. The state function after the measurement is, as always, one of the states of that observable; however, it is not a state function for the second observable. Measuring the second observable disturbs the system, and the state of the system is no longer one of the states of the first observable. In general, measuring the first observable again does not produce the same result as the first time. To sum up, both quantities cannot be known at the same time, and the two observables are said to be incompatible.

A specific example of this behaviour is the measurement of the component of angular momentum along two mutually perpendicular directions. The Stern-Gerlach experiment mentioned above involved measuring the angular momentum of a silver atom in the ground state. In reconstructing this experiment, a beam of silver atoms is passed between the poles of a magnet. The poles are shaped so that the magnetic field varies greatly in strength over a very small distance (Figure 63). The apparatus determines the m_s quantum number, which can be $+1/2$ or $-1/2$. No other values are obtained. Thus in this case the observable has only two states—*i.e.*, $N = 2$. The inhomogeneous magnetic field produces a force on the silver atoms in a direction that depends on the spin state of the atoms. The result is shown schematically in Figure 64. A beam of silver atoms is passed through magnet A. The atoms in the state with $m_s = +1/2$ are deflected upward and emerge as beam 1, while those with $m_s = -1/2$ are deflected downward and emerge as beam 2. If the direction of the magnetic field is the x-axis, the apparatus measures S_x, which is the x-component of spin angular momentum. The atoms in beam 1 have $S_x = +1/2\hbar$, while those in beam 2 have $S_x = -1/2\hbar$. In a classical picture, these two states represent atoms spinning about the direction of the x-axis with opposite senses of rotation.

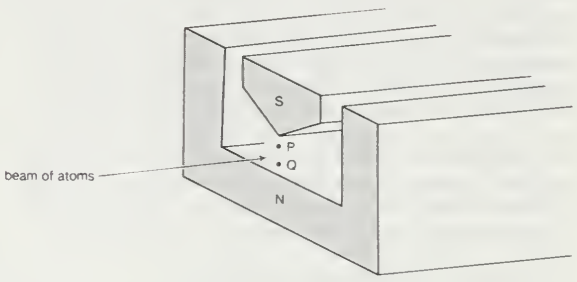

Figure 63: *Magnet in Stern-Gerlach experiment.* N and S are the north and south poles of a magnet. The knife-edge of S results in a much stronger magnetic field at the point P than at Q.

The y-component of spin angular momentum S_y also can have only the values $+1/2\hbar$ and $-1/2\hbar$; however, the two states of S_y are not the same as for S_x. In fact, each of the states of S_x is an equal mixture of the states for S_y, and conversely. Again, the two S_y states may be pictured as representing atoms with opposite senses of rotation about the y-axis. These classical pictures of quantum states are helpful, but only up to a certain point. For example, quantum theory says that each of the states corresponding to spin about the x-axis is a superposition of the two states with spin about the y-axis. There is no way to visualize this; it has absolutely no classical counterpart. One simply has to accept the result as a consequence of the axioms of the theory. Suppose that, as in Figure 64, the atoms in beam 1 are passed into a second magnet B, which has a magnetic field along the y-axis perpendicular to x. The atoms emerge from B and go in equal numbers through its two output channels. Classical theory says that the two magnets together have measured both the x- and y-components of spin angular momentum and that the atoms in beam 3 have $S_x = +1/2\hbar$, $S_y = +1/2\hbar$, while those in beam 4 have $S_x = +1/2\hbar$, $S_y = -1/2\hbar$. However, classical theory is wrong, because if beam 3 is put through still another magnet C, with its magnetic field along x, the atoms divide equally into beams 5 and 6 instead of emerging as a single beam 5 (as they would if they had $S_x = +1/2\hbar$). Thus, the correct statement is that the beam entering B has $S_x = +1/2\hbar$ and is composed of an equal mixture of the states $S_y = +1/2\hbar$ and $S_y = -1/2\hbar$—*i.e.*, the x-component of angular momentum is known but the y-component is not. Correspondingly, beam 3 leaving B has $S_y = +1/2\hbar$ and is an equal mixture of the states $S_x = +1/2\hbar$ and $S_x = -1/2\hbar$; the y-component of angular momentum is known but the x-component is not. The

information about S_x is lost because of the disturbance caused by magnet B in the measurement of S_y.

HEISENBERG UNCERTAINTY PRINCIPLE

The observables discussed so far have had discrete sets of experimental values. For example, the values of the energy of a bound system are always discrete, and angular momentum components have values that take the form $m\hbar$, where m is either an integer or a half-integer, positive or negative. On the other hand, the position of a particle or the linear momentum of a free particle can take continuous values in both quantum and classical theory. The mathematics of observables with a continuous spectrum of measured values is somewhat more complicated than for the discrete case but presents no problems of principle. An observable with a continuous spectrum of measured values has an infinite number of state functions. The state function Ψ of the system is still regarded as a combination of the state functions of the observable, but the sum in equation (187) must be replaced by an integral.

Measurements can be made of position x of a particle and the x-component of its linear momentum, denoted by p_x. These two observables are incompatible because they have different state functions. The phenomenon of diffraction noted above illustrates the impossibility of measuring position and momentum simultaneously and precisely. If a parallel monochromatic light beam passes through a slit (Figure 65A), its intensity varies with direction, as shown in Figure 65B. The light has zero intensity in certain directions. Wave theory shows that the first zero occurs at an angle θ_0, given by $\sin \theta_0 = \lambda/b$, where λ is the wavelength of the light and b is the width of the slit. If the width of the slit is reduced, θ_0 increases—*i.e.*, the diffracted light is more spread out. Thus, θ_0 measures the spread of the beam.

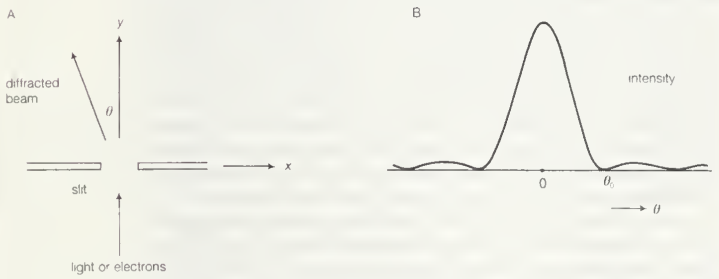

Figure 65: (A) Parallel monochromatic light incident normally on a slit, (B) variation in the intensity of the light with direction after it has passed through the slit. If the experiment is repeated with electrons instead of light, the same diagram would represent the variation in the intensity (*i.e.*, relative number) of the electrons.

Position-momentum uncertainty relation

The experiment can be repeated with a stream of electrons instead of a beam of light. According to Broglie, electrons have wavelike properties; therefore, the beam of electrons emerging from the slit should widen and spread out like a beam of light waves. This has been observed in experiments. If the electrons have velocity u in the forward direction (*i.e.*, the y-direction in Figure 65A), their (linear) momentum is $p = m_e u$. Consider p_x, the component of momentum in the x-direction. After the electrons have passed through the aperture, the spread in their directions results in an uncertainty in p_x by an amount

$$\Delta p_x \approx p \sin \theta_0 = p\frac{\lambda}{b}, \tag{188}$$

where λ is the wavelength of the electrons and, according to the Broglie formula, equals h/p. Thus, $\Delta p_x \approx h/b$. Exactly where an electron passed through the slit is unknown; it is only certain that an electron went through somewhere. Therefore, immediately after an electron goes through, the uncertainty in its x-position is $\Delta x \approx b/2$. Thus the product of the uncertainties is of the order of $\hbar$. More exact analysis shows that the product has a lower limit, given by

$$\Delta x \, \Delta p_x \geq \frac{\hbar}{2}. \tag{189}$$

This is the well-known Heisenberg uncertainty principle for position and momentum. It states that there is a limit to the precision with which the position and the momentum of an object can be measured at the same time. Depending on the experimental conditions, either quantity can be measured as precisely as desired (at least in principle), but the more precisely one of the quantities is measured, the less precisely the other is known.

The uncertainty principle is significant only on the atomic scale because of the small value of h in everyday units. If the position of a macroscopic object with a mass of, say one gram, is measured with a precision of 10^{-6} metre, the uncertainty principle states that its velocity cannot be measured to better than about 10^{-25} metre per second. Such a limitation is hardly worrisome. However, if an electron is located in an atom about 10^{-10} metre across, the principle gives a minimum uncertainty in the velocity of about 10^6 metre per second.

The above reasoning leading to the uncertainty principle is based on the wave-particle duality of the electron. When Heisenberg first propounded the principle in 1927 his reasoning was based, however, on the wave-particle duality of the photon. He considered the process of measuring the position of an electron by observing it in a microscope. Diffraction effects due to the wave nature of light result in a blurring of the image; the resulting uncertainty in the position of the electron is approximately equal to the wavelength of the light. To reduce this uncertainty, it is necessary to use light of shorter wavelength—*e.g.*, gamma rays. However, in producing an image of the electron, the gamma-ray photon bounces off the electron, giving the Compton effect (see above). As a result of the collision, the electron recoils in a statistically random way. The resulting uncertainty in the momentum of the electron is proportional to the momentum of the photon, which is inversely proportional to the wavelength of the photon. So it is again the case that increased precision in knowledge of the position of the electron is gained only at the expense of decreased precision in knowledge of its momentum. A detailed calculation of the process yields the same result as before (equation [189]). Heisenberg's reasoning brings out clearly the fact that the smaller the particle being observed, the more significant is the uncertainty principle. When a large body is observed, photons still bounce off it and change its momentum, but, considered as a fraction of the initial momentum of the body, the change is insignificant.

Energy-time uncertainty principle

The Schrödinger and Dirac theories give a precise value for the energy of each stationary state, but in reality the states do not have a precise energy. The only exception is in the ground (lowest energy) state. Instead, the energies of the states are spread over a small range. The spread arises from the fact that, because the electron can make a transition to another state, the initial state has a finite lifetime. The transition is a random process, and so different atoms in the same state have different lifetimes. If the mean lifetime is denoted as τ, the theory shows that the energy of the initial state has a spread of energy ΔE, given by

$$\tau \, \Delta E \approx \hbar. \tag{190}$$

This energy spread is manifested in a spread in the frequencies of emitted radiation. Therefore, the spectral lines are not infinitely sharp. (Some experimental factors can also broaden a line, but their effects can be reduced; however, the present effect, known as natural broadening, is fundamental and cannot be reduced.) Equation (190) is another type of Heisenberg uncertainty relation; generally, if a measurement with duration τ is made of the energy in a system, the measurement disturbs the system, causing the energy to be uncertain by an amount ΔE, the magnitude of which is given by the above equation.

QUANTUM ELECTRODYNAMICS

The application of quantum theory to the interaction between electrons and radiation requires a quantum treatment of Maxwell's field equations, which are the foundations of electromagnetism, and the relativistic theory of the electron formulated by Dirac (see above *Electron spin and antiparticles*). The resulting quantum field theory is known as quantum electrodynamics, or QED.

QED accounts for the behaviour and interactions of electrons, positrons, and photons. It deals with processes involving the creation of material particles from electromagnetic energy and with the converse processes in which a material particle and its antiparticle annihilate each other and produce energy. Initially the theory was beset with formidable mathematical difficulties, because the calculated values of quantities such as the charge and mass of the electron proved to be infinite. However, an ingenious set of techniques developed (in the late 1940s) by Hans Bethe, Julian S. Schwinger, Tomonaga Shin'ichirō, Richard P. Feynman, and others dealt systematically with the infinities to obtain finite values of the physical quantities. Their method is known as renormalization. The theory has provided some remarkably accurate predictions.

Renormalization

According to the Dirac theory, two particular states in hydrogen with different quantum numbers have the same energy. QED, however, predicts a small difference in their energies; the difference may be determined by measuring the frequency of the electromagnetic radiation that produces transitions between the two states. This effect was first measured by Willis E. Lamb, Jr., and Robert Retherford in 1947. Its physical origin lies in the interaction of the electron with the random fluctuations in the surrounding electromagnetic field. These fluctuations, which exist even in the absence of an applied field, are a quantum phenomenon. The accuracy of experiment and theory in this area may be gauged by two recent values for the separation of the two states, expressed in terms of the frequency of the radiation that produces the transitions:

experiment (1982)	1,057,858 ± 2 kilohertz
theory (1975)	1,057,864 ± 14 kilohertz.

An even more spectacular example of the success of QED is provided by the value for μ_e, the magnetic dipole moment of the free electron. Because the electron is spinning and has electric charge, it behaves like a tiny magnet, the strength of which is expressed by the value of μ_e. According to the Dirac theory, μ_e is exactly equal to $\mu_B = e\hbar/2m_e$, a quantity known as the Bohr magneton; however, QED predicts that $\mu_e = (1 + a)\mu_B$, where a is a small number, approximately $1/860$. Again, the physical origin of the QED correction is the interaction of the electron with random oscillations in the surrounding electromagnetic field. The best experimental determination of μ_e involves measuring not the quantity itself but the small correction term $\mu_e - \mu_B$. This greatly enhances the sensitivity of the experiment. The most recent results for the value of a are

experiment (1984)	$(115{,}965{,}219 \pm 1) \times 10^{-11}$
theory (1986)	$(115{,}965{,}227 \pm 10) \times 10^{-11}$.

Since a itself represents a small correction term, the magnetic dipole moment of the electron is measured with an accuracy of about one part in 10^{11}. One of the most precisely determined quantities in physics, the magnetic dipole moment of the electron can be calculated correctly from quantum theory to within about one part in 10^{10}.

The interpretation of quantum mechanics

Although quantum mechanics has been applied to problems in physics with great success, some of its ideas seem strange. A few of their implications are considered here.

THE ELECTRON: WAVE OR PARTICLE?

Young's aforementioned experiment in which a parallel beam of monochromatic light is passed through a pair of narrow parallel slits (Figure 66A) has an electron counterpart. In Young's original experiment, the intensity of the light varies with direction after passing through the slits (Figure 66B). The intensity oscillates because of interference between the light waves emerging from the two slits, the rate of oscillation depending on the wavelength of the light and the separation of the slits. The oscillation creates a fringe pattern of alternating light and dark bands that is modulated by the diffraction pattern from each slit. If one of the slits is covered, the interference fringes disappear, and only the diffraction pattern (shown as a broken line in Figure 66B) is observed.

Two-slit experiment

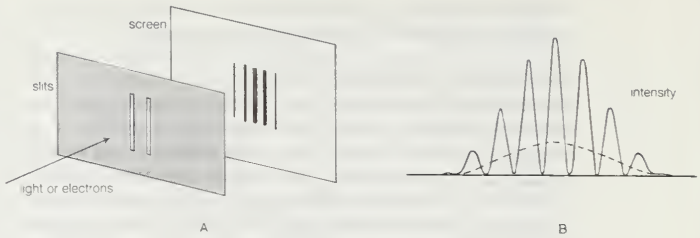

Figure 66: (A) Monochromatic light incident on a pair of slits gives interference fringes (alternate light and dark bands) on a screen. (B) variation in the intensity of the light at the screen when both slits are open. With a single slit, there is no interference pattern; the intensity variation is shown by the broken line. As with Figure 65B, the same diagram would give the variation in the intensity of electrons in the corresponding electron experiment.

Young's experiment can be repeated with electrons all with the same momentum. The screen in the optical experiment is replaced by a closely spaced grid of electron detectors. There are many devices for detecting electrons; the most common are scintillators. When an electron passes through a scintillating material, such as sodium iodide, the material produces a light flash which gives a voltage pulse that can be amplified and recorded. The pattern of electrons recorded by each detector is the same as that predicted for waves with wavelengths given by the Broglie formula. Thus, the experiment provides conclusive evidence for the wave behaviour of electrons.

If the experiment is repeated with a very weak source of electrons so that only one electron passes through the slits, a single detector registers the arrival of an electron. This is a well-localized event characteristic of a particle. Each time the experiment is repeated, one electron passes through the slits and is detected. A graph plotted with detector position along one axis and the number of electrons along the other looks exactly like the oscillating interference pattern in Figure 66B. Thus, the intensity function in the figure is proportional to the probability of the electron moving in a particular direction after it has passed through the slits. Apart from its units, the function is identical to Ψ^2, where Ψ is the solution of the time-independent Schrödinger equation for this particular experiment.

If one of the slits is covered, the fringe pattern disappears and is replaced by the diffraction pattern for a single slit. Thus, both slits are needed to produce the fringe pattern. However, if the electron is a particle, it seems reasonable to suppose that it passed through only one of the slits. The apparatus can be modified to ascertain which slit by placing a thin wire loop around each slit. When an electron passes through a loop, it generates a small electric signal, showing which slit it passed through. However, the interference fringe pattern then disappears, and the single-slit diffraction pattern returns. Since both slits are needed for the interference pattern to appear and since it is impossible to know which slit the electron passed through without destroying that pattern, one is forced to the conclusion that the electron goes through both slits at the same time.

In summary, the experiment shows both the wave and particle properties of the electron. The wave property predicts the probability of direction of travel before the electron is detected; on the other hand, the fact that the electron is detected in a particular place shows that it has particle properties. Therefore, the answer to the question whether the electron is a wave or a particle is that it is neither. It is an object exhibiting either wave or particle properties, depending on the type of measurement that is made on it. In other words, one cannot talk about the intrinsic properties of an electron; instead, one must consider the properties of the electron and measuring apparatus together.

Experimental proof of wave-particle duality

HIDDEN VARIABLES

A fundamental concept in quantum mechanics is that of randomness, or indeterminacy. In general, the theory predicts only the probability of a certain result. Consider the case of radioactivity. Imagine a box of atoms with identi-

The indeterminacy of quantum mechanics

cal nuclei that can undergo decay with the emission of an alpha particle. In a given time interval, a certain fraction will decay. The theory may tell precisely what that fraction will be, but it cannot predict which particular nuclei will decay. The theory asserts that, at the beginning of the time interval, all the nuclei are in an identical state and that the decay is a completely random process. Even in classical physics, many processes appear random. For example, one says that, when a roulette wheel is spun, the ball will drop at random into one of the numbered compartments in the wheel. Based on this belief, the casino owner and the players give and accept identical odds against each number for each throw. However, the fact is that the winning number could be predicted if one noted the exact location of the wheel when the croupier released the ball, the initial speed of the wheel, and various other physical parameters. It is only ignorance of the initial conditions and the difficulty of doing the calculations that makes the outcome appear to be random. In quantum mechanics, on the other hand, the randomness is asserted to be absolutely fundamental. The theory says that, though one nucleus decayed and the other did not, they were previously in the identical state.

Many eminent physicists, including Einstein, have not accepted this indeterminacy. They have rejected the notion that the nuclei were initially in the identical state. Instead, they postulated that there must be some other property—presently unknown, but existing nonetheless—that is different for the two nuclei. This type of unknown property is termed a hidden variable; if it existed, it would restore determinacy to physics. If the initial values of the hidden variables were known, it would be possible to predict which nuclei would decay. Such a theory would, of course, also have to account for the wealth of experimental data which conventional quantum mechanics explains from a few simple assumptions. Attempts have been made by Broglie, David Bohm, and others to construct theories based on hidden variables, but the theories are very complicated and contrived. For example, the electron would definitely have to go through only one slit in the two-slit experiment. To explain that interference occurs only when the other slit is open, it is necessary to postulate a special force on the electron which exists only when that slit is open. Such artificial additions make hidden variable theories unattractive, and there is little support for them among physicists.

The orthodox view of quantum mechanics—and the one adopted in the present article—is known as the Copenhagen interpretation because its main protagonist, Niels Bohr, worked in that city. The Copenhagen view of understanding the physical world stresses the importance of basing theory on what can be observed and measured experimentally. It therefore rejects the idea of hidden variables as quantities that cannot be measured. The Copenhagen view is that the indeterminacy observed in nature is fundamental and does not reflect an inadequacy in present scientific knowledge. One should therefore accept the indeterminacy without trying to "explain" it and see what consequences come from it.

Rejection of the notion of hidden variables

Attempts have been made to link the existence of free will with the indeterminacy of quantum mechanics, but it is difficult to see how this feature of the theory makes free will more plausible. On the contrary, free will presumably implies rational thought and decision, whereas the essence of the indeterminism in quantum mechanics is that it is due to intrinsic randomness.

PARADOX OF EINSTEIN, PODOLSKY, AND ROSEN

In 1935 Einstein and two other physicists in the United States, Boris Podolsky and Nathan Rosen, analyzed a thought experiment to measure position and momentum in a pair of interacting systems. Employing conventional quantum mechanics, they obtained some startling results, which led them to conclude that the theory does not give a complete description of physical reality. Their results, which are so peculiar as to seem paradoxical, are based on impeccable reasoning, but their conclusion that the theory is incomplete does not necessarily follow. Bohm simplified their experiment while retaining the central point of their reasoning; this discussion follows his account.

The proton, like the electron, has spin $\frac{1}{2}$; thus, no matter what direction is chosen for measuring the component of its spin angular momentum, the values are always $+\frac{1}{2}\hbar$ or $-\frac{1}{2}\hbar$. (The present discussion relates only to spin angular momentum, and the word spin is omitted from now on.) It is possible to obtain a system consisting of a pair of protons in close proximity and with total angular momentum equal to zero. Thus, if the value of one of the components of angular momentum for one of the protons is $+\frac{1}{2}\hbar$ along any selected direction, the value for the component in the same direction for the other particle must be $-\frac{1}{2}\hbar$. Suppose the two protons move in opposite directions until they are far apart. The total angular momentum of the system remains zero, and if the component of angular momentum along the same direction for each of the two particles is measured, the result is a pair of equal and opposite values. Therefore, after the quantity is measured for one of the protons, it can be predicted for the other proton: the second measurement is unnecessary. As previously noted, measuring a quantity changes the state of the system. Thus, if measuring S_x (the x-component of angular momentum) for proton 1 produces the value $+\frac{1}{2}\hbar$, the state of proton 1 after measurement corresponds to $S_x = +\frac{1}{2}\hbar$, and the state of proton 2 corresponds to $S_x = -\frac{1}{2}\hbar$. Any direction, however, can be chosen for measuring the component of angular momentum. Whichever direction is selected, the state of proton 1 after measurement corresponds to a definite component of angular momentum about that direction. Furthermore, since proton 2 must have the opposite value for the same component, it follows that the measurement on proton 1 results in a definite state for proton 2 relative to the chosen direction, notwithstanding the fact that the two particles may be millions of kilometres apart and are not interacting with each other at the time. Einstein and his two collaborators thought that this conclusion was so obviously false that the quantum mechanical theory on which it was based must be incomplete. They concluded that the correct theory would contain some hidden variable feature that would restore the determinism of classical physics.

Essential difference between quantum mechanics and classical physics

A comparison of how quantum theory and classical theory describe angular momentum for particle pairs illustrates the essential difference between the two outlooks. In both theories, if a system of two particles has a total angular momentum of zero, then the angular momenta of the two particles are equal and opposite. If the components of angular momentum are measured along the same direction, the two values are numerically equal, one positive and the other negative. Thus, if one component is measured, the other can be predicted. The crucial difference between the two theories is that, in classical physics, the system under investigation is assumed to have possessed the quantity being measured beforehand. The measurement does not disturb the system; it merely reveals the preexisting state. It may be noted that, if a particle were actually to possess components of angular momentum prior to measurement, such quantities would constitute hidden variables.

Does nature behave as quantum mechanics predicts? The answer comes from measuring the components of angular momenta for the two protons along different directions with an angle θ between them. A measurement on one proton can give only the result $+\frac{1}{2}\hbar$ or $-\frac{1}{2}\hbar$. The experiment consists of measuring correlations between the plus and minus values for pairs of protons with a fixed value of θ, and then repeating the measurements for different values of θ, as in Figure 67. The interpretation of the results rests on an important theorem by the British physicist John Stewart Bell. Bell began by assuming the existence of some form of hidden variable with a value that would determine whether the measured angular momentum gives a plus or minus result. He further assumed locality—namely, that measurement on one proton (*i.e.*, the choice of the measurement direction) cannot affect the result of the measurement on the other proton. Both these assumptions agree with classical, commonsense ideas. He then showed quite generally that these two assumptions lead to a certain relationship, now known as Bell's inequality, for the correlation values mentioned above. Experiments

Bell's inequality

have been conducted at several laboratories with photons instead of protons (the analysis is similar), and the results show fairly conclusively that Bell's inequality is violated. That is to say, the observed results agree with those of quantum mechanics and cannot be accounted for by a hidden variable (or deterministic) theory based on the concept of locality. One is forced to conclude that the two protons are a correlated pair and that a measurement on one affects the state of both, no matter how far apart they are. This may strike one as highly peculiar, but such is the way nature appears to be.

It may be noted that the effect on the state of proton 2 following a measurement on proton 1 is believed to be instantaneous; the effect happens before a light signal initiated by the measuring event at proton 1 reaches proton 2. Alain Aspect and his coworkers in Paris demonstrated this result in 1982 with an ingenious experiment in which the correlation between the two angular momenta was measured, within a very short time interval, by a high-frequency switching device. The interval was less than the time taken for a light signal to travel from one particle to the other at the two measurement positions. Einstein's special theory of relativity states that no message can travel with a speed greater than that of light. Thus, there is no way that the information concerning the direction of the measurement on the first proton could reach the second proton before the measurement was made on it.

MEASUREMENT IN QUANTUM MECHANICS

The way quantum mechanics treats the process of measurement has caused considerable debate. Schrödinger's time-dependent wave equation (equation [185]) is an exact recipe for determining the way the wave function varies with time for a given physical system in a given physical environment. According to the Schrödinger equation, the wave function varies in a strictly determinate way. On the other hand, in the axiomatic approach to quantum mechanics described above, a measurement changes the wave function abruptly and discontinuously. Before the measurement is made, the wave function Ψ is a mixture of the φs as indicated in equation (187). The measurement changes Ψ from a mixture of φs to a single φ. This change, brought about by the process of measurement, is termed the collapse or reduction of the wave function.

Collapse of the wave function Ψ

The collapse is a discontinuous change in Ψ; it is also unpredictable, because, starting with the same Ψ represented by the right-hand side of equation (187), the end result can be any one of the individual φs.

The Schrödinger equation, which gives a smooth and predictable variation of Ψ, applies between the measurements. The measurement process itself, however, cannot be described by the Schrödinger equation; it is somehow a thing apart. This appears unsatisfactory, inasmuch as a measurement is a physical process and ought to be the subject of the Schrödinger equation just like any other physical process.

The difficulty is related to the fact that quantum mechanics applies to microscopic systems containing one (or a few) electrons, protons, or photons. Measurements, however, are made with large-scale objects (*e.g.*, detectors, amplifiers, and meters) in the macroscopic world, which obeys the laws of classical physics. Thus, another way of formulating the question of what happens in a measurement is to ask how the microscopic quantum world relates and interacts with the macroscopic classical world. More narrowly, it can be asked how and at what point in the measurement process does the wave function collapse? So far, there are no satisfactory answers to these questions, although there are several schools of thought.

One approach stresses the role of a conscious observer in the measurement process and suggests that the wave function collapses when the observer reads the measuring instrument. Bringing the conscious mind into the measurement problem seems to raise more questions than it answers, however.

Copenhagen interpretation

As discussed above, the Copenhagen interpretation of the measurement process is essentially pragmatic. It distinguishes between microscopic quantum systems and macroscopic measuring instruments. The initial object or event—*e.g.*, the passage of an electron, photon, or atom—triggers the classical measuring device into giving a reading; somewhere along the chain of events, the result of the measurement becomes fixed (*i.e.*, the wave function collapses). This does not answer the basic question but says, in effect, not to worry about it. This is probably the view of most practicing physicists.

A third school of thought notes that an essential feature of the measuring process is irreversibility. This contrasts with the behaviour of the wave function when it varies according to the Schrödinger equation; in principle, any such variation in the wave function can be reversed by an appropriate experimental arrangement. However, once a classical measuring instrument has given a reading, the process is not reversible. It is possible that the key to the nature of the measurement process lies somewhere here. The Schrödinger equation is known to apply only to relatively simple systems. It is an enormous extrapolation to assume that the same equation applies to the large and complex system of a classical measuring device. It may be that the appropriate equation for such a system has features that produce irreversible effects (*e.g.*, wave-function collapse) which differ in kind from those for a simple system.

The many-worlds interpretation

One may also mention the so-called many-worlds interpretation, proposed by Hugh Everett III in 1957, which suggests that, when a measurement is made for a system in which the wave function is a mixture of states, the universe branches into a number of noninteracting universes. Each of the possible outcomes of the measurement occurs, but in a different universe. Thus, if $S_x = \hbar/2$ is the result of a Stern-Gerlach measurement on a silver atom (see above), there is another universe identical to ours in every way (including clones of people), except that the result of the measurement is $S_x = -\hbar/2$. Although this fanciful model solves some measurement problems, it has few adherents among physicists.

Because the various ways of looking at the measurement process lead to the same experimental consequences, trying to distinguish between them on scientific grounds may be fruitless. One or another may be preferred on the grounds of plausibility, elegance, or economy of hypotheses, but these are matters of individual taste. Whether one day a satisfactory quantum theory of measurement will emerge, distinguished from the others by its verifiable predictions, remains an open question.

Applications of quantum mechanics

As has been noted, quantum mechanics has been enormously successful in explaining microscopic phenomena in all branches of physics. The three phenomena described in this section are examples that demonstrate the quintessence of the theory.

DECAY OF THE K^0 MESON

The K^0 meson, discovered in 1953, is produced in high-energy collisions between nuclei and other particles. It has zero electric charge, and its mass is about one-half the mass of the proton. It is unstable and, once formed, rapidly decays into either 2 or 3 pi-mesons. The average lifetime of the K^0 is about 10^{-10} second.

In spite of the fact that the K^0 meson is uncharged, quantum theory predicts the existence of an antiparticle with the same mass, decay products, and average lifetime; the

antiparticle is denoted by $\bar{K}^0$. During the early 1950s, several physicists questioned the justification for postulating the existence of two particles with such similar properties. In 1955, however, Murray Gell-Mann and Abraham Pais made an interesting prediction about the decay of the K^0 meson. Their reasoning provides an excellent illustration of the quantum mechanical axiom that the wave function Ψ can be a superposition of states; in this case, there are two states, the K^0 and $\bar{K}^0$ mesons themselves.

A K^0 meson may be represented formally by writing the wave function as $\Psi = K^0$; similarly $\Psi = \bar{K}^0$ represents a $\bar{K}^0$. From the two states, K^0 and $\bar{K}^0$, the following two new states are constructed:

$$K_1 = \frac{(K^0 + \bar{K}^0)}{\sqrt{2}}, \tag{191a}$$

$$K_2 = \frac{(K^0 - \bar{K}^0)}{\sqrt{2}}. \tag{191b}$$

From these two equations it follows that

$$K^0 = \frac{(K_1 + K_2)}{\sqrt{2}}, \tag{191c}$$

$$\bar{K}^0 = \frac{(K_1 - K_2)}{\sqrt{2}}. \tag{191d}$$

The reason for defining the two states K_1 and K_2 is that, according to quantum theory, when the K^0 decays, it does not do so as an isolated particle; instead, it combines with its antiparticle to form the states K_1 and K_2. The state K_1 decays into two pi-mesons with a very short lifetime (about 10^{-10} second), while K_2 decays into three pi-mesons with a longer lifetime (about 10^{-7} second).

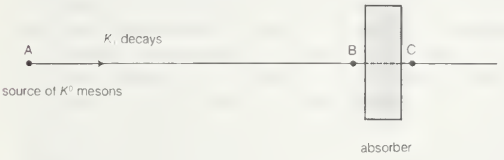

Figure 68: Decay of the K^0 meson.

The physical consequences of these results may be demonstrated in the following experiment. K^0 particles are produced in a nuclear reaction at the point A (Figure 68). They move to the right in the figure and start to decay. At point A, the wave function is $\Psi = K^0$, which, from equation (191c), can be expressed as the sum of K_1 and K_2. As the particles move to the right, the K_1 state begins to decay rapidly. If the particles reach point B in about 10^{-8} second, nearly all the K_1 component has decayed, although hardly any of the K_2 component has done so. Thus, at point B, the beam has changed from one of pure K^0 to one of almost pure K_2, which equation (191b) shows is an equal mixture of K^0 and $\bar{K}^0$. In other words, $\bar{K}^0$ particles appear in the beam simply because K_1 and K_2 decay at different rates. At point B, the beam enters a block of absorbing material. Both the K^0 and $\bar{K}^0$ are absorbed by the nuclei in the block, but the $\bar{K}^0$ are absorbed more strongly. As a result, even though the beam is an equal mixture of K^0 and $\bar{K}^0$ when it enters the absorber, it is almost pure K^0 when it exits at point C. The beam thus begins and ends as K^0.

Gell-Mann and Pais predicted all this, and experiments subsequently verified it. The experimental observations are that the decay products are primarily two pi-mesons with a short decay time near A, three pi-mesons with longer decay time near B, and two pi-mesons again near C. (This account exaggerates the changes in the K_1 and K_2 components between A and B and in the K^0 and $\bar{K}^0$ components between B and C; the argument, however, is unchanged.) The phenomenon of generating the $\bar{K}^0$ and regenerating the K_1 decay is purely quantum. It rests on the quantum axiom of the superposition of states and has no classical counterpart.

CESIUM CLOCK

Quantum oscillation frequency

The cesium clock is the most accurate type of clock yet developed. This device makes use of transitions between the spin states of the cesium nucleus and produces a frequency which is so regular that it has been adopted for establishing the time standard.

Like electrons, many atomic nuclei have spin. The spin of these nuclei produces a set of small effects in the spectra, known as hyperfine structure. (The effects are small because, though the angular momentum of a spinning nucleus is of the same magnitude as that of an electron, its magnetic moment, which governs the energies of the atomic levels, is relatively small.) The nucleus of the cesium atom has spin quantum number $^7/_2$. The total angular momentum of the lowest energy states of the cesium atom is obtained by combining the spin angular momentum of the nucleus with that of the single valence electron in the atom. (Only the valence electron contributes to the angular momentum because the angular momenta of all the other electrons total zero. Another simplifying feature is that the ground states have zero orbital momenta, so only spin angular momenta need to be considered.) When nuclear spin is taken into account, the total angular momentum of the atom is characterized by a quantum number, conventionally denoted by F, which for cesium is 4 or 3. These values come from the spin value $^7/_2$ for the nucleus and $^1/_2$ for the electron. If the nucleus and the electron are visualized as tiny spinning tops, the value $F = 4$ ($^7/_2 + {}^1/_2$) corresponds to the tops spinning in the same sense, and $F = 3$ ($^7/_2 - {}^1/_2$) corresponds to spins in opposite senses. The energy difference ΔE of the states with the two F values is a precise quantity. If electromagnetic radiation of frequency ν_0, where

$$h\nu_0 = \Delta E, \tag{192}$$

is applied to a system of cesium atoms, transitions will occur between the two states. An apparatus that can detect the occurrence of transitions thus provides an extremely precise frequency standard. This is the principle of the cesium clock.

Principle of the cesium clock

The apparatus is shown schematically in Figure 69. A beam of cesium atoms emerges from an oven at a temperature of about 100° C. The atoms pass through an inhomogeneous magnet A, which deflects the atoms in state $F = 4$ downward and those in state $F = 3$ by an equal amount upward. The atoms pass through slit S and continue into a second inhomogeneous magnet B. Magnet B is arranged so that it deflects atoms with an unchanged state in the same direction that magnet A deflected them. The atoms follow the paths indicated by the broken lines in the figure and are lost to the beam. However, if an alternating electromagnetic field of frequency ν_0 is applied to the beam as it traverses the centre region C, transitions between states will occur. Some atoms in state $F = 4$ will change to $F = 3$, and vice versa. For such atoms, the deflections in magnet B are reversed. The atoms follow the whole lines in the diagram and strike a tungsten wire, which gives electric signals in proportion to the number of cesium atoms striking the wire. As the frequency ν of the alternating field is varied, the signal has a sharp maximum for $\nu = \nu_0$. The length of the apparatus from

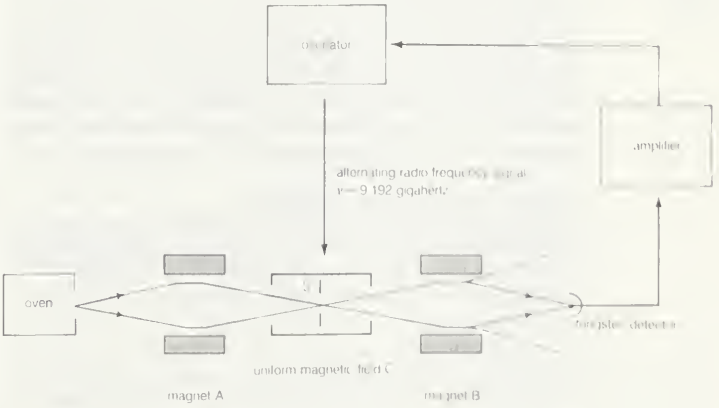

Figure 69: Cesium clock.

the oven to the tungsten detector is about one metre.

Each atomic state is characterized not only by the quantum number F but also by a second quantum number m_F. For $F = 4$, m_F can take integral values from 4 to -4. In the absence of a magnetic field, these states have the same energy. A magnetic field, however, causes a small change in energy proportional to the magnitude of the field and to the m_F value. Similarly, a magnetic field changes the energy for the $F = 3$ states according to the m_F value which, in this case, may vary from 3 to -3. The energy changes are indicated in Figure 70. In the cesium clock, a weak constant magnetic field is superposed on the alternating electromagnetic field in region C. The theory shows that the alternating field can bring about a transition only between pairs of states with m_F values that are the same or that differ by unity. However, as can be seen from the figure, the only transitions occurring at the frequency ν_0 are those between the two states with $m_F = 0$. The apparatus is so sensitive that it can discriminate easily between such transitions and all the others.

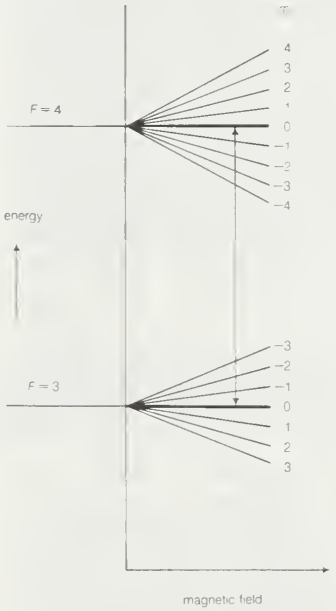

Figure 70: Variation of energy with magnetic-field strength for the $F = 4$ and $F = 3$ states in cesium-133.

If the frequency of the oscillator drifts slightly so that it does not quite equal ν_0, the detector output drops. The change in signal strength produces a signal to the oscillator to bring the frequency back to the correct value. This servo system keeps the oscillator frequency automatically locked to ν_0.

The cesium clock is exceedingly stable. The frequency of the oscillator remains constant to about one part in 10^{13}. For this reason, the device has been used to redefine the second. This base unit of time in the SI system is defined as equal to 9,192,631,770 cycles of the radiation corresponding to the transition between the levels $F = 4$, $m_F = 0$ and $F = 3$, $m_F = 0$ of the ground state of the cesium-133 atom. Prior to 1964, the second was defined in terms of the motion of the Earth. The latter, however, is not nearly as stable as the cesium clock. Specifically, the fractional variation of the Earth's rotation is a few hundred times larger than that of the frequency of the cesium clock.

Definition of the second

A QUANTUM VOLTAGE STANDARD

Quantum theory has been used to establish a voltage standard, and this standard has proven to be extraordinarily accurate and consistent from laboratory to laboratory.

If two layers of superconducting material are separated by a thin insulating barrier, a supercurrent (*i.e.*, a current of paired electrons) can pass from one superconductor to the other. This is another example of the tunneling process described earlier. Several effects based on this phenomenon were predicted in 1962 by the British physicist Brian D. Josephson. Demonstrated experimentally soon afterwards, they are now referred to as the Josephson effects.

If a DC (direct-current) voltage V is applied across the two superconductors, the energy of an electron pair changes by an amount of $2eV$ as it crosses the junction. As a result, the supercurrent oscillates with frequency ν given by the Planck relationship—equation (176). Thus,

$$2eV = h\nu. \qquad (193)$$

The AC Josephson effect

This oscillatory behaviour of the supercurrent is known as the AC (alternating-current) Josephson effect. Measurement of V and ν permits a direct verification of the Planck relationship. Although the oscillating supercurrent has been detected directly, it is extremely weak. A more sensitive method of investigating equation (193) is to study effects resulting from the interaction of microwave radiation with the supercurrent.

Several carefully conducted experiments have verified equation (193) to such a high degree of precision that it has been used to determine the value of $2e/h$. This value can in fact be determined more precisely by the AC Josephson effect than by any other method. The result is so reliable that laboratories now employ the AC Josephson effect to set a voltage standard. The numerical relationship between V and ν is

$$\frac{2e}{h} = \frac{\nu}{V} = 483{,}597.7 \times 10^9 \text{ hertz per volt.}$$

In this way, measuring a frequency, which can be done with great precision, gives the value of the voltage. Before the Josephson method was used, the voltage standard in metrological laboratories devoted to the maintenance of physical units was based on high-stability Weston cadmium cells. These cells, however, tend to drift and so caused inconsistencies between standards in different laboratories. The Josephson method has provided a standard giving agreement to within a few parts in 10^8 for measurements made at different times and in different laboratories.

The experiments described in the preceding two sections are only two examples of high-precision measurements in physics. The values of the fundamental constants, such as c, h, e, and m_e, are determined from a wide variety of experiments based on quantum phenomena. The results are so consistent that the values of the constants are thought to be known in most cases to better than one part in 10^6. Physicists may not know what they are doing when they make a measurement, but they do it extremely well. (G.L.S.)

BIBLIOGRAPHY

Classical mechanics. The history of classical mechanics is chronicled in I. BERNARD COHEN, *The Newtonian Revolution* (1980); and E.J. DIJKSTERHUIS, *The Mechanization of the World Picture* (1961; originally published in Dutch, 1950). All introductory physics textbooks contain a portion on classical mechanics; recent examples include HANS C. OHANIAN, *Physics*, 2nd ed. (1989); and ROBERT RESNICK, DAVID HALLIDAY, and KENNETH S. KRANE, *Physics*, 4th ed. (1992). The principal reference for classical mechanics is S. FRAUTSCHI *et al.*, *The Mechanical Universe: Mechanics and Heat*, advanced ed. (1986). Other texts include, at an introductory level, A.P. FRENCH, *Newtonian Mechanics* (1971); and at a more advanced, graduate-school level, HERBERT GOLDSTEIN, *Classical Mechanics*, 2nd ed. (1980), a standard text that contains a lengthy, detailed bibliography of more specialized books dealing with specific aspects of the subject. (D.L.G.)

Celestial mechanics. Modern introductory treatments and discussions of some advanced techniques and classic developments include J.M.A. DANBY, *Fundamentals of Celestial Mechanics*, 2nd ed., rev. and enlarged (1988); DIRK BROUWER and GERALD M. CLEMENCE, *Methods of Celestial Mechanics* (1961); and HENRY CROZIER KEATING PLUMMER, *An Introductory Treatise on Dynamical Astronomy* (1918, reprinted 1960). Orbital resonances are discussed in two review articles by S.J. PEALE: "Orbital Resonances in Solar-System," *Annual Review of Astronomy and Astrophysics*, 14:215–246 (1976), and "Orbital Resonances, Unusual Configurations, and Exotic Rotation States Among Planetary Satellites," in JOSEPH A. BURNS and MILDRED SHAPLEY MATTHEWS (eds.), *Satellites* (1986), pp. 159–223. Current practice in solving the n-body problem on computers is given in the introduction to a paper by LARS HERNQUIST, "Performance Characteristics of Tree Codes," *The*

Astrophysical Journal: Supplement Series, 64(4):715–734 (August 1987). An introduction to modern dynamics involving chaos and an introduction to algebraic maps is given by MICHEL HENON, "Numerical Exploration of Hamiltonian Systems," in GÉRARD IOOSS, ROBERT H.G. HELLEMAN, and RAYMOND STORA (eds.), *Chaotic Behaviour in Deterministic Systems* (1983), pp. 54–170. Readable accounts of examples of chaotic dynamics in celestial mechanics are found in two articles by JACK WISDOM: "Chaotic Dynamics in the Solar-System," *Icarus,* 72(2):241–275 (1987), and "Chaotic Behaviour in the Solar System," in M.V. BERRY, I.C. PERCIVAL, and N.O. WEISS (eds.), *Dynamical Chaos* (1987), pp. 109–129. A simple discussion of tides and tidal evolution is given by S.J. PEALE, "Consequences of Tidal Evolution," in MARGARET G. KIVELSON (ed.), *The Solar System: Observations and Interpretations* (1986), pp. 275–288. Advanced discussions of tidal evolution analysis as applied to the Earth are given by KURT LAMBECK, *The Earth's Variable Rotation: Geophysical Causes and Consequences* (1980). (S.J.P.)

Relativistic mechanics. An outstanding work containing an account of the special theory of relativity is ABRAHAM PAIS, *"Subtle Is the Lord—": The Science and Life of Albert Einstein* (1982). Some good introductions at the undergraduate level are W. RINDLER, *Essential Relativity: Special, General, and Cosmological,* 2nd ed. (1977); JAMES H. SMITH, *Introduction to Special Relativity* (1965); EDWIN F. TAYLOR and JOHN ARCHIBALD WHEELER, *Spacetime Physics* (1966). More substantial treatises are J. AHARONI, *The Special Theory of Relativity,* 2nd ed. (1965, reprinted 1985); and J.L. SYNGE, *Relativity: The Special Theory,* 2nd ed. (1965). (G.W.G.)

Mechanics of solids. There are a number of works on the history of the subject. A.E.H. LOVE, *A Treatise on the Mathematical Theory of Elasticity,* 4th ed. (1927, reprinted 1944), has a well-researched chapter on the origin of elasticity up to the early 1900s. STEPHEN P. TIMOSHENKO, *History of Strength of Materials: With a Brief Account of the History of Theory of Elasticity and Theory of Structures* (1953, reprinted 1983), provides good coverage of most subfields of solid mechanics up to the period around 1940, including in some cases detailed but quite readable accounts of specific developments and capsule biographies of major figures. C. TRUESDELL, *Essays in the History of Mechanics* (1968), summarizes his studies of original source materials on Jakob Bernoulli (1654–1705), Leonhard Euler, Leonardo da Vinci, and others and connects those contributions to some of the developments in what he calls "rational mechanics" as of the middle 1900s. Two articles in *Handbuch der Physik* provide historical background: C. TRUESDELL and R.A. TOUPIN, "The Classical Field Theories," vol. 3, pt. 1 (1960); and C. TRUESDELL and W. NOLL, "The Nonlinear Field Theories of Mechanics," vol. 3, pt. 3 (1965).

There are many good books for beginners on the subject, intended for the education of engineers; one that stands out for its coverage of inelastic solid mechanics as well as the more conventional topics on elementary elasticity and structures is STEPHEN H. CRANDALL, NORMAN C. DAHL, and THOMAS J. LARDNER (eds.), *An Introduction to the Mechanics of Solids,* 2nd ed., with SI units (1978). Those with an interest in the physics of materials might begin with A.H. COTTRELL, *The Mechanical Properties of Matter* (1964, reprinted 1981). Some books for beginners aim for a more general introduction to continuum mechanics, including solids and fluids; one such text is Y.C. FUNG, *A First Course in Continuum Mechanics,* 2nd ed. (1977). A readable introduction to continuum mechanics at a more advanced level, such as might be used by scientists and engineers from other fields or by first-year graduate students, is LAWRENCE E. MALVERN, *Introduction to the Mechanics of a Continuous Medium* (1969). The article by TRUESDELL and TOUPIN, mentioned above, provides a comprehensive, perhaps overwhelming, treatment of continuum mechanics fundamentals.

For more specialized treatment of linear elasticity, the classics are the work by LOVE, mentioned above; STEPHEN P. TIMOSHENKO and J.N. GOODIER, *Theory of Elasticity,* 3rd ed. (1970); and N.I. MUSKHELISHVILI, *Some Basic Problems of the Mathematical Theory of Elasticity,* 2nd ed. (1963, reprinted 1977; originally published in Russian, 4th corrected and augmented ed., 1954). The article by TRUESDELL and NOLL noted above is a good source on finite elasticity and also on viscoelastic fluids; a standard reference on the latter is R. BYRON BIRD *et al., Dynamics of Polymeric Liquids,* vol. 1, *Fluid Mechanics,* 2nd ed. (1987). Other books generally regarded as classics in their subfields are R. HILL, *The Mathematical Theory of Plasticity* (1950, reissued 1983); J.C. JAEGER and N.G. COOK, *Fundamentals of Rock Mechanics,* 3rd ed. (1979). JOHN PRICE HIRTH and JENS LOTHE, *Theory of Dislocations,* 2nd ed. (1982); and KEIITI AKI and PAUL G. RICHARDS, *Quantitative Seismology,* 2 vol. (1980). Other aspects of stress waves in solids are covered by J.D. ACHENBACH, *Wave Propagation in Elastic Solids* (1973). In addition, the scope of finite element analysis in solid mechanics and many other areas can be gleaned from O.C. ZIENKIEWICZ and R.L. TAYLOR, *The Finite Element Method,* 4th ed., 2 vol. (1989–91); and that of fracture mechanics from MELVIN F. KANNINEN and CARL H. POPELAR, *Advanced Fracture Mechanics* (1985). Structural mechanics and issues relating to stability and elastic-plastic stress-strain relations in a way that updates the book by Hill are presented by ZDEŇEK P. BĂZANT and LUIGI CEDOLIN, *Stability of Structures: Elastic, Inelastic, Fracture, and Damage Theories* (1991). (J.R.R.)

Fluid mechanics. A classic text which enshrines all the results of 19th-century fluid dynamics is HORACE LAMB, *Hydrodynamics,* 6th ed. (1932, reissued 1945). This remains useful, but many later books, besides being more up-to-date, provide a better-balanced perspective of the subject and have better illustrations. N. CURLE and H.J. DAVIES, *Modern Fluid Dynamics,* vol. 1, *Incompressible Flow* (1968); and G.K. BATCHELOR, *Introduction to Fluid Dynamics* (1967, reissued 1973), can both be recommended to serious students who are not put off by mathematics. D.J. TRITTON, *Physical Fluid Dynamics,* 2nd ed. (1988), adopts a somewhat different approach and contains interesting material on turbulence and convective instabilities. Readers who are interested in the practical aspects of the subject and who want information concerning hydrostatics as well as fluid dynamics should consult one of the many good texts intended for engineers; among these, B.S. MASSEY, *Mechanics of Fluids,* 5th ed. (1983), is excellent. The development of the subject as a practical science is traced in HUNTER ROUSE and SIMON INCE, *History of Hydraulics* (1957, reprinted 1980). (T.E.F.)

Quantum mechanics. Scholarly but lively accounts of the early history of the subject are JAGDISH MEHRA and HELMUT RECHENBERG, *The Historical Development of Quantum Theory* (1982–), of which 5 vol. in 7 had appeared by 1992, covering the period from 1900 to 1926; and MAX JAMMER, *The Conceptual Development of Quantum Mechanics* (1966). The authors had the advantage, not usually accorded to historians, of being able to talk to their subjects.

There are a number of excellent texts on quantum mechanics at the undergraduate and graduate level. The following is a selection, beginning with the more elementary: A.P. FRENCH and EDWIN F. TAYLOR, *An Introduction to Quantum Physics* (1978); ALASTAIR I.M. RAE, *Quantum Mechanics,* 2nd ed. (1986); EUGEN MERZBACHER, *Quantum Mechanics,* 2nd ed. (1970); and ANTHONY SUDBERY, *Quantum Mechanics and the Particles of Nature: An Outline for Mathematicians* (1986), rather mathematical but including useful accounts and summaries of quantum metaphysics. RICHARD P. FEYNMAN, ROBERT B. LEIGHTON, and MATTHEW SANDS, *The Feynman Lectures on Physics,* vol. 3, *Quantum Mechanics* (1965), is a personal and stimulating look at the subject. A good introduction to quantum electrodynamics is RICHARD P. FEYNMAN, *QED: The Strange Theory of Light and Matter* (1985).

J.C. POLKINGHORNE, *The Quantum World* (1984); and JOHN GRIBBIN, *In Search of Schrödinger's Cat: Quantum Physics and Reality* (1984), are both highly readable and instructive books written at a popular level. BERNARD D'ESPAGNAT, *Conceptual Foundations of Quantum Mechanics,* 2nd ed. (1976), is a technical account of the fundamental conceptual problems involved. The proceedings of a conference, *New Techniques and Ideas in Quantum Measurement Theory,* ed. by DANIEL M. GREENBERGER (1986), contain a wide-ranging set of papers that deal with both the experimental and theoretical aspects of the measurement problem.

Applications are presented by H. HAKEN and H.C. WOLF, *Atomic and Quantum Physics: An Introduction to the Fundamentals of Experiment and Theory,* 2nd enlarged ed. (1987; originally published in German, 2nd rev. and enlarged ed., 1983); EMILIO SEGRÈ, *Nuclei and Particles: An Introduction to Nuclear and Subnuclear Physics,* 2nd rev. and enlarged ed. (1977, reissued 1980); DONALD H. PERKINS, *Introduction to High Energy Physics,* 3rd ed. (1987); CHARLES KITTEL, *Introduction to Solid State Physics,* 6th ed. (1986); and RODNEY LOUDON, *The Quantum Theory of Light,* 2nd ed. (1983). B.W. PETLEY, *The Fundamental Physical Constants and the Frontier of Measurement* (1985), gives a good account of present knowledge of the fundamental constants. (G.L.S.)

Medicine

Until the revolutionary scientific discoveries of the 19th and 20th centuries, medical practice was generally restricted to folk medicine and proscriptive religious and cultural tenets and limited by uneven knowledge and religious beliefs. As modern, empirical science took into its province the human body and its ills, "medicine" came to refer to the aggregate of scientific fields related to prevention and treatment of disease, as well as maintenance of health.

The many important discoveries in human anatomy and physiology, infectious and other diseases, drugs, and therapeutic procedures that took place during the 19th and 20th centuries have had a direct bearing on the important developments that occurred in the field of public health. Philanthropists, social activists, and government officials began to take a critical look at the living conditions of the poor, the ill, and the working class and joined in a positive effort toward reform and education. The laws enacted during this period gradually brought about clean water, safer living conditions, lower morbidities and mortalities, preventive medicine, and a decrease in the incidence of infectious diseases.

Medical education for physicians and other health-care professionals has generally kept pace with advances in medicine, especially in the developed countries. Each country in the world maintains its own requirements for medical degrees and licenses, and medical boards and councils have been formed to set standards and oversee the quality of medical education. Boards of certification have created stringent requirements that physicians must meet before they can practice a specialty, and they put great stress on the need for practicing physicians to continue their education as well.

A disparity in medical services is especially obvious between developed and developing countries. This disparity is the product of many problems, involving finances, communication, education, and cultural and religious views. International organizations such as the World Health Organization and the United Nations International Children's Fund make substantial progress in medical services by, among other things, considering the customs and culture in developing countries as an integral factor in the formation of the most efficient national health-care delivery system.

The concept of a general institution for the care of the sick can be traced to the Middle Ages, when monks set aside areas of their monasteries for this purpose. The modern general hospital fulfills a wide range of needs for the community both on an inpatient and an outpatient basis. The complexity and dynamic nature of medical practice is reflected in the growing number of specialty areas of the average general hospital. Teaching also has become a concern of many general hospitals, and, when designed as such, teaching hospitals provide services and knowledge often unavailable in other general hospitals.

Although religious and cultural laws as well as ethics have always been important in medicine, it was not until the 1960s that the modern legal system became intimately involved in medical practice. Advances in therapeutics and diagnostics have created legal and moral issues in such complex areas as abortion, euthanasia, and patients' rights. Physicians have had to reexamine the ethical tenets by which their predecessors practiced medicine and to develop new standards by which they may be judged.

THE HISTORY OF MEDICINE AND SURGERY

Medicine and surgery before 1800

PRIMITIVE MEDICINE AND FOLKLORE

Unwritten history is not easy to interpret, and, although much may be learned from a study of the drawings, bony remains, and surgical tools of early man, it is difficult to reconstruct his mental attitude toward the problems of disease and death. It seems probable that humans, as soon as they had reached the stage of reasoning, discovered, by the process of trial and error, which plants might be used as foods, which of them were poisonous, and which of them had some medicinal value. Folk medicine or domestic medicine, consisting largely in the use of vegetable products, or herbs, originated in this fashion and still persists.

But that is not the whole story. Man did not at first regard death and disease as natural phenomena. Common maladies, such as colds or constipation, were accepted as part of existence and dealt with by means of such herbal remedies as were available. Serious and disabling diseases, however, were placed in a very different category. These were of supernatural origin. They might be the result of a spell cast upon the victim by some enemy, visitation by a malevolent demon, or the work of an offended god who had either projected some object—a dart, a stone, a worm—into the body of the victim or had abstracted something, usually the soul of the patient. The treatment then applied was to lure the errant soul back to its proper habitat within the body or to extract the evil intruder, be it dart or demon, by counterspells, incantations, potions, suction, or other means.

Belief in supernatural causes of illness

One curious method of providing the disease with means of escape from the body was by making a hole, 2.5 to five centimetres across, in the skull of the victim—the practice of trepanning, or trephining. Trepanned skulls of prehistoric date have been found in Britain, France, and other parts of Europe and in Peru. Many of them show evidence of healing and, presumably, of the patient's survival. The practice still exists among primitive people in parts of Algeria, in Melanesia, and perhaps elsewhere, though it is fast becoming extinct.

Magic and religion played a large part in the medicine of prehistoric or primitive man. Administration of a vegetable drug or remedy by mouth was accompanied by incantations, dancing, grimaces, and all the tricks of the magician. Therefore, the first doctors, or "medicine men," were witch doctors or sorcerers. The use of charms and talismans, still prevalent in modern times, is of ancient origin.

Apart from the treatment of wounds and broken bones, the folklore of medicine is probably the most ancient aspect of the art of healing, for primitive physicians showed their wisdom by treating the whole person, soul as well as body. Treatments and medicines that produced no physical effects on the body could nevertheless make a patient feel better when both medicine man and patient believed in their efficacy. This so-called placebo effect is applicable even in modern clinical medicine.

THE ANCIENT MIDDLE EAST AND EGYPT

The establishment of the calendar and the invention of writing marked the dawn of recorded history. The clues to early knowledge are scanty, consisting of clay tablets bearing cuneiform signs and seals that were used by physicians of ancient Mesopotamia. In the Louvre there is preserved a stone pillar on which is inscribed the Code of Hammurabi, who was a Babylonian king of the 18th century BC. This code includes laws relating to the practice of medicine, and the penalties for failure were severe. For example, "If the doctor, in opening an abscess, shall kill the patient, his hands shall be cut off"; if, however, the patient was a slave, the doctor was simply obliged to supply another slave.

The Greek historian Herodotus stated that every Babylonian was an amateur physician, since it was the custom to lay the sick in the street so that anyone passing by might offer advice. Divination, from the inspection of the liver of a sacrificed animal, was widely practiced to foretell the course of a disease. Little else is known regarding Babylonian medicine, and the name of not a single physician has survived.

The physician Imhotep

When the medicine of ancient Egypt is examined, the picture becomes clearer. The first physician to emerge is Imhotep, chief minister to King Djoser in the 3rd millen-

nium BC, who designed one of the earliest pyramids, the Step Pyramid at Ṣaqqārah, and who was later regarded as the Egyptian god of medicine and identified with the Greek god Asclepius. Surer knowledge comes from the study of Egyptian papyri, especially the Ebers and Edwin Smith papyri discovered in the 19th century. The former is a list of remedies, with appropriate spells or incantations, while the latter is a surgical treatise on the treatment of wounds and other injuries.

Contrary to what might be expected, the widespread practice of embalming the dead body did not stimulate study of human anatomy. The preservation of mummies has, however, revealed some of the diseases suffered at that time, including arthritis, tuberculosis of the bone, gout, tooth decay, bladder stones, and gallstones; there is evidence too of the parasitic disease schistosomiasis, which remains a scourge still. There seems to have been no syphilis or rickets.

The search for information on ancient medicine leads naturally from the papyri of Egypt to Hebrew literature. Though the Bible contains little on the medical practices of Old Testament times, it is a mine of information on social and personal hygiene. The Jews were indeed pioneers in matters of public health. (D.J.G./P.Rh.)

TRADITIONAL MEDICINE AND SURGERY IN THE ORIENT

India. Indian medicine has a long history. Its earliest concepts are set out in the sacred writings called the Vedas, especially in the metrical passages of the Atharvaveda, which may possibly date as far back as the 2nd millennium BC. According to a later writer, the system of medicine called Āyurveda was received by a certain Dhanvantari from Brahma, and Dhanvantari was deified as the god of medicine. In later times his status was gradually reduced, until he was credited with having been an earthly king who died of snakebite.

The period of Vedic medicine lasted until about 800 BC. The Vedas are rich in magical practices for the treatment of diseases and in charms for the expulsion of the demons traditionally supposed to cause diseases. The chief conditions mentioned are fever (*takman*), cough, consumption, diarrhea, dropsy, abscesses, seizures, tumours, and skin diseases (including leprosy). The herbs recommended for treatment are numerous.

The golden age of Indian medicine, from 800 BC until about AD 1000, was marked especially by the production of the medical treatises known as the *Caraka-saṃhitā* and *Suśruta-saṃhitā,* attributed, respectively, to Caraka, a physician, and Suśruta, a surgeon. Estimates place the *Caraka-saṃhitā* in its present form as dating from the 1st century AD, although there were earlier versions. The *Suśruta-saṃhitā* probably originated in the last centuries BC and had become fixed in its present form by the 7th century AD. Of somewhat lesser importance are the treatises attributed to Vagbhata. All later writings on Indian medicine were based on these works.

Because Hindus were prohibited by their religion from cutting the dead body, their knowledge of anatomy was limited. The *Suśruta-saṃhitā* recommends that a body be placed in a basket and sunk in a river for seven days. On its removal the parts could be easily separated without cutting. As a result of these crude methods, the emphasis in Hindu anatomy was given first to the bones and then to the muscles, ligaments, and joints. The nerves, blood vessels, and internal organs were very imperfectly known.

The Hindu view of the body

The Hindus believed that the body contains three elementary substances, microcosmic representatives of the three divine universal forces, which they called spirit (air), phlegm, and bile (comparable to the humours of the Greeks). Health depends on the normal balance of these three elementary substances. The seven primary constituents of the body—blood, flesh, fat, bone, marrow, chyle, and semen—are produced by the action of the elementary substances. Semen was thought to be produced from all parts of the body and not from any individual part or organ.

Both Caraka and Suśruta state the existence of a large number of diseases (Suśruta says 1,120). Rough classifications of diseases are given. In all texts "fever," of which numerous types are described, is regarded as important. Phthisis (wasting disease, especially pulmonary tuberculosis) was apparently prevalent, and the Hindu physicians knew the symptoms of cases likely to terminate fatally. Smallpox was common, and it is probable that smallpox inoculation was practiced.

Hindu physicians employed all five senses in diagnosis. Hearing was used to distinguish the nature of the breathing, alteration in voice, and the grinding sound produced by the rubbing together of broken ends of bones. They appear to have had a good clinical sense, and their discourses on prognosis contain acute references to symptoms that have grave import. Magical beliefs still persisted, however, until late in the classical period; thus, the prognosis could be affected by such fortuitous factors as the cleanliness of the messenger sent to fetch the physician, the nature of his conveyance, or the types of persons the physician met on his journey to the patient.

Dietetic treatment was important and preceded any medicinal treatment. Fats were much used, internally and externally. The most important methods of active treatment were referred to as the "five procedures": the administration of emetics, purgatives, water enemas, oil enemas, and sneezing powders. Inhalations were frequently administered, as were leeching, cupping, and bleeding.

The Indian materia medica was extensive and consisted mainly of vegetable drugs, all of which were from indigenous plants. Caraka knew 500 medicinal plants, and Suśruta knew 760. But animal remedies (such as the milk of various animals, bones, gallstones) and minerals (sulfur, arsenic, lead, copper sulfate, gold) were also employed. The physicians collected and prepared their own vegetable drugs. Among those that eventually appeared in Western pharmacopoeias were cardamom and cinnamon.

As a result of the strict religious beliefs of the Hindus, hygienic measures were important in treatment. Two meals a day were decreed, with indications of the nature of the diet, the amount of water to be drunk before and after the meal, and the use of condiments. Bathing and care of the skin were carefully prescribed, as were cleansing of the teeth with twigs from named trees, anointing of the body with oil, and the use of eyewashes.

Hindu surgery

In surgery, ancient Hindu medicine reached its zenith. Operations performed by Hindu surgeons included excision of tumours, incision and draining of abscesses, punctures to release fluid in the abdomen, extraction of foreign bodies, repair of anal fistulas, splinting of fractures, amputations, cesarean sections, and stitching of wounds.

A broad array of surgical instruments were used. According to Suśruta the surgeon should be equipped with 20 sharp and 101 blunt instruments of various descriptions. The instruments were largely of steel. Alcohol seems to have been used as a narcotic during operations, and bleeding was stopped by hot oils and tar.

In two types of operations especially, the Hindus were outstanding. Stone in the bladder (vesical calculus) was common in ancient India, and the surgeons frequently removed the stones by lateral lithotomy. They also introduced plastic surgery. Amputation of the nose was one of the prescribed punishments for adultery, and repair was carried out by cutting from the patient's cheek or forehead a piece of tissue of the required size and shape and applying it to the stump of the nose. The results appear to have been tolerably satisfactory, and the modern operation is certainly derived indirectly from this ancient source. Hindu surgeons also operated on cataracts by couching, or displacing the lens to improve vision.

China. The Chinese system of medicine is of great antiquity and is independent of any recorded external influences. According to legend, Emperor Huang Ti (the Yellow Emperor) wrote the canon of internal medicine called the *Nei ching* in the 3rd millennium BC; but there is some evidence that in its present form it dates from no earlier than the 3rd century BC. Most of the Chinese medical literature is founded on the *Nei ching,* and it is still regarded as a great authority. Other famous works are the *Mo ching* (known in the West as the "Pulse Classic"), composed about AD 300; and the *Golden Mirror,* a compilation, made about AD 1700, of medical writings of the

Han dynasty (202 BC–AD 220). European medicine began to obtain a footing in China early in the 19th century, but the native system is still widely practiced.

The yin–yang principle

Basic to traditional Chinese medicine is the dualistic cosmic theory of the yin and the yang. The yang, the male principle, is active and light and is represented by the heavens; the yin, the female principle, is passive and dark and is represented by the earth. The human body, like matter in general, is made up of five elements: wood, fire, earth, metal, and water. With these are associated other groups of five, such as the five planets, the five conditions of the atmosphere, the five colours, and the five tones. Health, character, and the success of all political and private ventures are determined by the preponderance, at the time, of the yin or the yang; and the great aim of ancient Chinese medicine is to control their proportions in the body.

The teachings of the religious sects forbade the mutilation of the dead human body; hence traditional anatomy rests on no sure scientific foundation. One of the most important writers on anatomy, Wang Ch'ing-jen, gained his knowledge from the inspection of dog-torn children who had died in a plague epidemic in AD 1798. Traditional Chinese anatomy is based on the cosmic system, which postulates the presence of such hypothetical structures as the 12 channels and the three so-called burning spaces. The body contains five organs (heart, lungs, liver, spleen, and kidneys), which store up but do not eliminate; and five viscera (such as the stomach, intestines, gallbladder, and bladder), which eliminate but do not store up. Each organ is associated with one of the planets, colours, tones, smells, and tastes. There are 365 bones and 365 joints in the body.

According to the physiology of traditional Chinese medicine, the blood vessels contain blood and air, in proportions varying with those of the yin and the yang. These two cosmic principles circulate in the 12 channels and control the blood vessels and hence the pulse. The *Nei ching* says that "the blood current flows continuously in a circle and never stops. It may be compared to a circle without beginning or end." On this insubstantial evidence it has been claimed that the Chinese anticipated Harvey's discovery of the circulation of the blood. Traditional Chinese pathology is also dependent on the theory of the yin and the yang; this led to an elaborate classification of diseases in which most of the types listed are without scientific foundation.

In diagnosis, detailed questions are asked about the history of the illness and about such things as the patient's taste, smell, and dreams. Conclusions are drawn from the quality of the voice, and note is made of the colour of the face and of the tongue. The most important part of the investigation, however, is the examination of the pulse. Wang Shu-ho, who wrote the "Pulse Classic," lived in the 3rd century BC, and innumerable commentaries were written on his work. The pulse is examined in several places, at different times, and with varying degrees of pressure. The operation may take as long as three hours. It is often the only examination made, and it is used both for diagnosis and for prognosis. Not only are the diseased organs ascertained but the time of death or recovery may be foretold.

The pulse doctrine

The Chinese materia medica has always been extensive and consists of vegetable, animal (including human), and mineral remedies. There were famous herbals from ancient times; but all these, to the number of about 1,000, were embodied by Li Shih-chen in the compilation of *Pen-ts'ao kang-mu* (the "Great Pharmacopoeia") in the 16th century AD. This work, in 52 volumes, has been frequently revised and reprinted and is still authoritative. The use of drugs is mainly to restore the harmony of the yin and the yang and is also related to such matters as the five organs, the five planets, and the five colours. The art of prescribing is therefore complex.

Among the drugs taken over by Western medicine from the Chinese are rhubarb, iron (for anemia), castor oil, kaolin, aconite, camphor, and *Cannabis sativa* (Indian hemp). Chaulmoogra oil was used by the Chinese for leprosy from at least the 14th century, and about a century ago it began to be used for this purpose by Western physicians. The herb mahuang (*Ephedra vulgaris*) has been used in China for at least 4,000 years, and the isolation of the alkaloid ephedrine from it has greatly improved the Western treatment of asthma and similar conditions.

The most famous and expensive of Chinese remedies is ginseng. Western analysis has shown that it has diuretic and other properties but is of doubtful value. In recent years reserpine, the active principle of the Chinese plant *Rauwolfia*, has been isolated; it is now effectively used in the treatment of high blood pressure and some emotional and mental conditions.

Hydrotherapy is probably of Chinese origin, since cold baths were used for fevers as early as 180 BC. The inoculation of smallpox matter, in order to produce a mild but immunizing attack of the disease, was practiced in China from ancient times and came to Europe about 1720. Another treatment is moxibustion, which consists in making a small, moistened cone (moxa) of powdered leaves of mugwort, or wormwood (*Artemisia* species), applying it to the skin, igniting it, and then crushing it into the blister so formed. Other substances are also used for the moxa. Dozens of these are sometimes applied at one sitting. The practice is often associated with acupuncture.

Acupuncture

Acupuncture consists of the insertion into the skin and underlying tissues of a metal needle, either hot or cold. The theory is that the needle affects the distribution of the yin and the yang in the hypothetical channels and burning spaces of the body. The site of the insertion is chosen to affect a particular organ or organs. The practice of acupuncture dates from before 2500 BC and is peculiarly Chinese. Little of practical importance has been added since that date, although there have been many well-known treatises on the subject.

A bronze model, *c.* AD 860, shows the hundreds of specified points for the insertion of the needle; this was the forerunner of countless later models and diagrams. The needles used are three to 24 centimetres (about one to nine inches) in length. They are often inserted with considerable force and after insertion may be agitated or screwed to the left or right. Acupuncture, often combined with moxibustion, is still widely used for many diseases, including fractures. Recently people in the Western world have turned to acupuncturists for relief from pain and other symptoms. There is some speculation that the treatment may trigger the brain to release morphinelike substances called endorphins, which presumably reduce the feeling of pain and its concomitant emotions.

Japan. The most interesting features of Japanese medicine are the extent to which it was derivative and the rapidity with which, after a slow start, it became westernized and scientific. In the early pre-Christian Era disease was regarded as sent by the gods or produced by the influence of evil spirits. Treatment and prevention were based largely on religious practices, such as prayers, incantations, and exorcism; at a later date drugs and bloodletting were also employed.

Beginning in AD 608, when young Japanese physicians were sent to China for a long period of study, Chinese influence on Japanese medicine was paramount. In 982, Tamba Yasuyori completed the 30-volume *Ishinhō*, the oldest Japanese medical work still extant. This work discusses diseases and their treatment, classified mainly according to the affected organs or parts. It is based entirely on older Chinese medical works, with the yin and yang concept underlying the theory of disease causation.

In 1570 a 15-volume medical work was published by Menase Dōsan, who also wrote at least five other works. In the most significant of these, the *Keitekishū* (a manual of the practice of medicine, 1574), diseases—or sometimes merely symptoms—are classified and described in 51 groups; the work is unusual in that it includes a section on the diseases of old age. Another distinguished physician and teacher of the period, Nagata Tokuhun, whose important books were the *I-no-ben* (1585) and the *Baika mujinzo* (1611), held that the chief aim of the medical art was to support the natural force, and consequently that it was useless to persist with stereotyped methods of treatment unless the physician had the cooperation of the patient.

European influences

European medicine was introduced into Japan in the 16th century by Jesuit missionaries and again in the 17th century by Dutch physicians. Translations of European books on anatomy and internal medicine were made in the 18th century, and in 1836 an influential Japanese work on physiology appeared. In 1857 a group of Dutch-trained Japanese physicians founded a medical school in Edo (later Tokyo) that is regarded as the beginning of the medical faculty of the Imperial University of Tokyo.

During the last third of the 18th century it became government policy to westernize Japanese medicine, and great progress was made in the foundation of medical schools and the encouragement of research. Important medical breakthroughs by the Japanese followed, among them the discovery of the plague bacillus in 1894, the discovery of a dysentery bacillus in 1897, the isolation of adrenaline (epinephrine) in crystalline form in 1901, and the first experimental production of a tar-induced cancer in 1918.

THE ROOTS OF WESTERN MEDICINE

Early Greece. The transition from magic to science was a gradual process that lasted for centuries, and there is little doubt that ancient Greece inherited much from Babylonia and Egypt, and even India and China. Twentieth-century readers of the Homeric tales the *Iliad* and the *Odyssey* may well be bewildered by the narrow distinction between gods and men among the characters and between historical fact and poetic fancy in the story. Two characters, the military surgeons Podaleirius and Machaon, are said to have been sons of Asclepius, the god of medicine. The divine Asclepius may have originated in a human Asclepius who lived about 1200 BC and is said to have performed many miracles of healing.

Asclepius was worshiped in hundreds of temples throughout Greece, the remains of which may still be seen at Epidaurus, Cos, Athens, and elsewhere. To these resorts, or hospitals, sick persons went for the healing ritual known as incubation, or temple sleep. They lay down to sleep in the dormitory, or *abaton*, and were visited in their dreams by Asclepius or by one of his priests, who gave advice. In the morning the patient often is said to have departed cured. There are at Epidaurus many inscriptions recording cures, though there is no mention of failures or deaths.

Cure by incubation

Diet, baths, and exercises played their part in the treatment, and it would appear that these temples were the prototype of modern health resorts. Situated in a peaceful spot, with gardens and fountains, each had its theatre for amusements and its stadium for athletic contests. The cult of incubation continued far into the Christian Era. In Greece, some of the Aegean islands, Sardinia, and Sicily, sick persons are still taken to spend a night in certain churches in the hope of a cure.

It was, however, the work of the early philosophers, rather than that of the priests of Asclepius, that impelled Greeks to refuse to be guided solely by supernatural influence and moved them to seek out for themselves the causes and reasons for the strange ways of nature. The 6th-century philosopher Pythagoras, whose chief discovery was the importance of numbers, also investigated the physics of sound, and his views influenced the medical thought of his time. In the 5th century BC Empedocles set forth the view that the universe is composed of four elements—fire, air, earth, and water; this conception led to the doctrine of the four bodily humours: blood; phlegm; choler, or yellow bile; and melancholy, or black bile. The maintenance of health was held to depend upon the harmony of the four humours.

Hippocrates. Medical thought had reached this stage and had partially discarded the conceptions based upon magic and religion by 460 BC, the year that Hippocrates is said to have been born. Although he has been called the father of medicine, little is known of his life, and there may, in fact, have been several men of this name; or Hippocrates may have been the author of only some, or none, of the books that make up the Hippocratic Collection (*Corpus Hippocraticum*). Ancient writers held that Hippocrates taught and practiced medicine in Cos, the island of his birth, and in other parts of Greece, including Athens, and that he died at an advanced age.

Whether Hippocrates was one man or several, the works attributed to him mark the stage in Western medicine where disease was coming to be regarded as a natural rather than a supernatural phenomenon and doctors were encouraged to look for physical causes of illness. Some of the works, notably the *Aphorismi* (*Aphorisms*), were used as textbooks until the 19th century. The first and best-known aphorism is, "Life is Short, Art long, Occasion sudden and dangerous, Experience deceitful, and Judgment difficult" (often shortened to the Latin tag, "Ars longa, vita brevis"). This is followed by brief comments on diseases and symptoms, many of which remain valid.

The thermometer and the stethoscope were not then known; nor, indeed, did Hippocrates employ any aid to diagnosis beyond his own powers of observation and logical reasoning. He had an extraordinary ability to foretell the course of a malady, and he laid more stress upon the expected outcome, or prognosis, of a disease than upon its identification, or diagnosis. He had no patience with the idea that disease was a punishment sent by the gods. Writing of epilepsy, then called "the sacred disease," he said, "It is not any more sacred than other diseases, but has a natural cause, and its supposed divine origin is due to man's inexperience. Every disease," he continued, "has its own nature, and arises from external causes."

Hippocrates noted the effect of food, of occupation, and especially of climate in causing disease, and one of his most interesting books, entitled *De aëre, aquis et locis* (*Air, Waters and Places*), would today be classed as a treatise on human ecology. Pursuing this line of thought, Hippocrates stated that "our natures are the physicians of our diseases" and advocated that this tendency to natural cure should be fostered. He laid much stress on diet and the use of few drugs. He knew well how to describe illness clearly and concisely and recorded failures as well as successes; he viewed disease with the eye of the naturalist and studied the entire patient in his environment.

The Hippocratic oath

Perhaps the greatest legacy of Hippocrates is the charter of medical conduct embodied in the so-called Hippocratic oath, which has been adopted as a pattern by physicians throughout the ages:

> I swear by Apollo the physician, and Asclepius, and Health, and All-heal, and all the gods and goddesses . . . to reckon him who taught me this Art equally dear to me as my parents, to share my substance with him, and relieve his necessities if required; to look upon his offspring in the same footing as my own brothers, and to teach them this art, if they shall wish to learn it, without fee or stipulation; and that by precept, lecture, and every other mode of instruction, I will impart a knowledge of the Art to my own sons, and those of my teachers, and to disciples bound by a stipulation and oath according to the law of medicine, but to none others. I will follow that system of regimen which, according to my ability and judgment, I consider for the benefit of my patients, and abstain from whatever is deleterious and mischievous. I will give no deadly medicine to any one if asked, nor suggest any such counsel; and in like manner I will not give to a woman a pessary to produce abortion. . . . Into whatever houses I enter, I will go into them for the benefit of the sick, and will abstain from every voluntary act of mischief and corruption; and, further from the seduction of females or males, of freemen and slaves. Whatever, in connection with my professional practice or not, in connection with it, I see or hear, in the life of men, which ought not to be spoken of abroad, I will not divulge, as reckoning that all such should be kept secret.

Not strictly an oath, it was, rather, an ethical code or ideal, an appeal for right conduct. In one or other of its many versions, it has guided the practice of medicine throughout the world for more than 2,000 years.

Hellenistic and Roman medicine. In the following century the work of Aristotle, regarded as the first great biologist, was of inestimable value to medicine. A pupil of Plato at Athens and tutor to Alexander the Great, Aristotle studied the entire world of living things. He laid what can be identified as the foundations of comparative anatomy and embryology, and his views influenced scientific thinking for the next 2,000 years.

After the time of Aristotle, the centre of Greek culture shifted to Alexandria, where a famous medical school was

established in about 300 BC. There, the two best medical teachers were Herophilus, whose treatise on anatomy may have been the first of its kind, and Erasistratus, regarded by some as the founder of physiology. Erasistratus noted the difference between sensory and motor nerves but thought that the nerves were hollow tubes containing fluid and that air entered the lungs and heart and was carried through the body in the arteries. Alexandria continued as a centre of medical teaching even after the Roman Empire had attained supremacy over the Greek world, and medical knowledge remained predominantly Greek.

Asclepiades of Bithynia (born 124 BC) differed from Hippocrates in that he denied the healing power of nature and insisted that disease should be treated safely, speedily, and agreeably. An opponent of the humoral theory, he drew upon the atomic theory of the 5th-century Greek philosopher Democritus in advocating a doctrine of *strictum et laxum*—the attribution of disease to the contracted or relaxed condition of the solid particles that he believed make up the body. To restore harmony among the particles and thus effect cures, Asclepiades used typically Greek remedies: massage, poultices, occasional tonics, fresh air, and corrective diet. He gave particular attention to mental disease, clearly distinguishing hallucinations from delusions. He released the insane from confinement in dark cellars and prescribed a regimen of occupational therapy, soothing music, soporifics (especially wine), and exercises to improve the attention and memory.

Asclepiades did much to win acceptance for Greek medicine in Rome. Aulus Cornelius Celsus, the Roman nobleman who wrote *De medicina* about AD 30, gave a classic account of Greek medicine of the time, including descriptions of elaborate surgical operations. His book, overlooked in his day, enjoyed a wide reputation during the Renaissance.

Galen

During the early centuries of the Christian Era, Greek doctors thronged to Rome. The most illustrious of them was Galen, who began practicing there in AD 161. He acknowledged his debt to Hippocrates and followed the Hippocratic method, accepting the doctrine of the humours. He laid stress on the value of anatomy, and he virtually founded experimental physiology. Galen recognized that the arteries contain blood and not merely air. He showed how the heart sets the blood in motion in an ebb and flow fashion, but he had no idea that the blood circulates. Dissection of the human body was at that time illegal, so that he was forced to base his knowledge upon the examination of animals, particularly apes. A voluminous writer who stated his views forcibly and with confidence, he remained for centuries the undisputed authority from whom no one dared to differ.

Another influential physician of the 2nd century AD was Soranus of Ephesus, who wrote authoritatively on childbirth, infant care, and women's diseases. An opponent of abortion, he advocated numerous means of contraception. He also described how to assist a difficult delivery by turning the fetus in the uterus (podalic version), a life-saving technique that was subsequently lost sight of until it was revived in the 16th century.

Although the contribution of Rome to the practice of medicine was negligible compared with that of Greece, in matters of public health the Romans set the world a great example. The city of Rome had an unrivaled water supply. Gymnasiums and public baths were provided, and there was even domestic sanitation and adequate disposal of sewage. The army had its medical officers, public physicians were appointed to attend the poor, and hospitals were built; a Roman hospital excavated near Düsseldorf, Ger., was found to be strikingly modern in design.

CHRISTIAN AND MUSLIM RESERVOIRS OF LEARNING

After the fall of Rome, learning was no longer held in high esteem, experiment was discouraged, and originality became a dangerous asset. During the early Middle Ages medicine passed into the widely diverse hands of the Christian Church and Arab scholars.

Translators and saints. It is sometimes stated that the early Christian Church had an adverse effect upon medical progress. Disease was regarded as a punishment for sin, and such chastening demanded only prayer and repentance. Moreover, the human body was held sacred and dissection was forbidden. But the infinite care and nursing bestowed upon the sick under Christian auspices must outweigh any intolerance shown toward medicine in the early days.

Preservation of Greek medical manuscripts

Perhaps the greatest service rendered to medicine by the church was the preservation and transcription of the classical Greek medical manuscripts. These were translated into Latin in many medieval monasteries, and the Nestorian Christians (an Eastern church) established a school of translators to render the Greek texts into Arabic. This famous school, and also a great hospital, were located at Jundi Shāhpūr in southwest Persia, where the chief physician was Jurjīs ibn Bukhtīshūʿ, the first of a dynasty of translators and physicians that lasted for six generations. A later translator of great renown was Ḥunayn ibn Isḥāq, or Johannitus (born AD 809), whose translations were said to be worth their weight in gold.

About this time there appeared a number of saints whose names were associated with miraculous cures. Among the earliest of these were twin brothers, Cosmas and Damian, who suffered martyrdom (*c.* AD 303) and who became the patron saints of medicine. Other saints were invoked as powerful healers of certain diseases, such as St. Vitus for chorea (or St. Vitus' dance) and St. Anthony for erysipelas (or St. Anthony's fire). The cult of these saints was widespread in medieval times, and a later cult, that of St. Roch for plague, was widespread during the plague-ridden years of the 14th century.

Arabian medicine. A second reservoir of medical learning during those times was the great Muslim empire, which extended from Persia to Spain. Although it is customary to speak of Arabian medicine in describing this period, not all of the physicians were Arabs or natives of Arabia. Nor, indeed, were they all Muslims: some were Jews, some Christians, and they were drawn from all parts of the empire. One of the earliest figures was Rhazes, a Persian born in the last half of the 9th century near modern Tehrān, who wrote a voluminous treatise on medicine, *Kitāb al-ḥāwī* ("Comprehensive Book"), but whose most famous work, *De variolis et morbillis* (*A Treatise on the Smallpox and Measles*), distinguishes between these two diseases and gives a clear description of both.

Avicenna

Of later date was Avicenna (980–1037), also a Persian, who has been called the prince of physicians and whose tomb at Hamadan has become a place of pilgrimage. He could repeat the Qur'ān before he was 10 years old and at the age of 18 became court physician. His principal medical work, *al-Qānūn fī aṭ-ṭibb* (*The Canon of Medicine*), became a classic and was used at many medical schools—at Montpellier, Fr., as late as 1650—and reputedly is still used in the East.

The greatest contribution of Arabian medicine was in chemistry and in the knowledge and preparation of medicines. The chemists of that time were alchemists, and their pursuit was mainly a search for the philosopher's stone, which supposedly would turn common metals into gold. In the course of their experiments, however, numerous substances were named and characterized, and some were found to have medicinal value. Many drugs now in use are of Arab origin, as are such processes as distillation and sublimation.

At that period, and indeed throughout most historical times, surgery was considered inferior to medicine, and surgeons were held in low regard. The renowned Spanish surgeon Abū al-Qāsim (Albucasis), however, did much to raise the status of surgery in Córdoba, an important centre of commerce and culture with a hospital and medical school equal to those of Cairo and Baghdad. A careful and conservative practitioner, he wrote the first illustrated surgical text, which held wide influence in Europe for centuries.

Another great doctor of Córdoba, born in the 12th century, just as the sun of Arabian culture was setting, was the Jewish philosopher Maimonides. Banished from the city because he would not become a Muslim, he eventually went to Cairo, where the law was more lenient and where he acquired a reputation so high that he became physician

to Saladin, the Saracen leader. (He was the original of El Hakim in Sir Walter Scott's *Talisman*.) A few of his works, written in Arabic, were eventually translated into Latin and printed; perhaps the best known is *Yad-Hachazakah*, or *The Code of Maimonides*, an ethical guide still esteemed in Jewish medical circles.

MEDIEVAL AND RENAISSANCE EUROPE

Salerno and the medical schools. At about the same time that Arabian medicine flourished, the first organized medical school in Europe was established at Salerno, in southern Italy. Although the school of Salerno produced no brilliant genius and no startling discovery, it was the outstanding medical institution of its time and the parent of the great medieval schools soon to be founded at Montpellier and Paris, in France, and at Bologna and Padua, in Italy. Salerno drew scholars from near and far. Remarkably liberal in some of its views, Salerno admitted women as medical students. The school owed much to the enlightened Holy Roman emperor Frederick II, who decreed in 1221 that no one should practice medicine until he had been publicly approved by the masters of Salerno.

The Salernitan school also produced a literature of its own; the best-known work, of uncertain date and of composite authorship, was the *Regimen Sanitatis Salernitanum* ("Salernitan Guide to Health"). Written in verse, it has appeared in numerous editions and has been translated into many languages. Among its oft-quoted couplets is the following:

> Use three physicians still, first Doctor Quiet,
> Next Doctor Merryman, and Doctor Diet.

Montpellier

Salerno yielded its place as the premier medical school of Europe to Montpellier in about 1200. John of Gaddesden, the model for the "doctour of physick" in Chaucer's *Canterbury Tales*, was one of the English students there. That he relied upon astrology and upon the doctrine of the humours is evident from Chaucer's description:

> Well could he guess the ascending of the star
> Wherein his patient's fortunes settled were.
> He knew the course of every malady,
> Were it of cold or heat or moist or dry.

Medieval physicians analyzed symptoms, examined excreta, and made their diagnoses. Then they might prescribe diet, rest, sleep, exercise, or baths; or they could administer emetics and purgatives or bleed the patient. Surgeons could treat fractures and dislocations, repair hernias, and perform amputations and a few other operations. Some of them prescribed opium, mandragora, or alcohol to deaden pain. Childbirth was left to midwives, who relied on folklore and tradition.

Great hospitals were established during the Middle Ages by religious foundations, and infirmaries were attached to abbeys, monasteries, priories, and convents. Doctors and nurses in these institutions were members of religious orders and combined spiritual with physical healing.

The spread of new learning. Among the teachers of medicine in the medieval universities there were many who clung to the past, but there were not a few who determined to explore new lines of thought. The new learning of the Renaissance, born in Italy, grew and expanded slowly. Two great 13th-century scholars who influenced medicine were Roger Bacon, an active observer and tireless experimenter, and Albertus Magnus, a distinguished philosopher and scientific writer.

About this time Mondino dei Liucci taught at Bologna. Prohibitions against human dissection were slowly lifting, and Mondino performed his own dissections rather than following the customary procedure of entrusting the task to a menial. Although he perpetuated the errors of Galen, his *Anothomia*, published in 1316, was the first practical manual of anatomy. Foremost among the surgeons of the day was Guy de Chauliac, a physician to three popes at Avignon. His *Chirurgia magna* ("Great Surgery"), based on observation and experience, had a profound influence upon the progress of surgery.

The Renaissance in the 14th, 15th, and 16th centuries was much more than just a reviving of interest in Greek and Roman culture; it was rather a change of outlook, an eagerness for discovery, a desire to escape from the limitations of tradition and to explore new fields of thought and action. In medicine, it was perhaps natural that anatomy and physiology, the knowledge of the human body and its workings, should be the first aspects of medical learning to receive attention from those who realized the need for reform.

Vesalius

It was in 1543 that Andreas Vesalius, a young Belgian professor of anatomy at the University of Padua, published *De humani corporis fabrica* ("On the Structure of the Human Body"). Based on his own dissections, this seminal work corrected many of Galen's errors. By his scientific observations and methods, Vesalius showed that Galen could no longer be regarded as the final authority. His work at Padua was continued by Gabriel Fallopius and, later, by Hieronymus Fabricius ab Aquapendente; it was his work on the valves in the veins, *De venarum ostiolis* (1603), that suggested to his pupil William Harvey his revolutionary theory of the circulation of the blood, one of the great medical discoveries.

Surgery profited from the new outlook in anatomy, and the great reformer Ambroise Paré dominated the field in the 16th century. Paré was surgeon to four kings of France, and he has deservedly been called the father of modern surgery. In his autobiography, written after he had retired from 30 years of service as an army surgeon, Paré described how he had abolished the painful practice of cautery to stop bleeding and used ligatures and dressings instead. His favourite expression, "I dressed him; God healed him," is characteristic of this humane and careful doctor.

In Britain during this period surgery, which was performed by barber-surgeons, was becoming regulated and organized under royal charters. Companies were thus formed that eventually became the royal colleges of surgeons in Scotland and England. Physicians and surgeons united in a joint organization in Glasgow, and a college of physicians was founded in London.

The 16th-century medical scene was enlivened by the enigmatic physician and alchemist who called himself Paracelsus. Born in Switzerland, he traveled extensively throughout Europe, gaining medical skills and practicing and teaching as he went. In the tradition of Hippocrates, Paracelsus stressed the power of nature to heal; but unlike Hippocrates he believed also in the power of supernatural forces, and he violently attacked the medical treatments of his day. Eager for reform, he allowed his intolerance to outweigh his discretion, as when he prefaced his lectures at Basel by publicly burning the works of Avicenna and Galen. The authorities and medical men were understandably outraged. Widely famous in his time, Paracelsus remains a controversial figure to this day. Despite his turbulent career, however, he did attempt to bring a more rational approach to diagnosis and treatment, and he introduced the use of chemical drugs in place of herbal remedies.

Fracastoro on syphilis

A contemporary of Paracelsus, Girolamo Fracastoro of Italy was a scholar cast from a very different mold. His account of the disease syphilis, entitled *Syphilis sive morbus Gallicus* (1530; "Syphilis or the French Disease"), was written in verse. Although Fracastoro called syphilis the French disease, others called it the Neapolitan disease, for it was said to have been brought to Naples from America by the sailors of Christopher Columbus. Its origin is still questioned, however. Fracastoro was interested in epidemic infection, and he offered the first scientific explanation of disease transmission. In his great work, *De contagione et contagiosis morbis* (1546), he theorized that the seeds of certain diseases are imperceptible particles transmitted by air or by contact.

THE ENLIGHTENMENT

In the 17th century the natural sciences moved forward on a broad front. There were attempts to grapple with the nature of science, as expressed in the works of thinkers like Francis Bacon, Descartes, and Newton. New knowledge of chemistry superseded the theory that all things are made up of earth, air, fire, and water, and the old Aristotelian ideas began to be discarded. The supreme 17th-century

achievement in medicine was Harvey's explanation of the circulation of blood.

Harvey and the experimental method. Born in Folkestone, Eng., William Harvey studied at Cambridge University and then spent several years at Padua, where he came under the influence of Fabricius. He established a successful medical practice in London and by precise observation and scrupulous reasoning developed his theory of circulation. In 1628 he published his classic book *Exercitatio Anatomica de Motu Cordis et Sanguinis in Animalibus* (*Concerning the Motion of the Heart and Blood*), often called *De Motu Cordis*.

That the book aroused controversy is not surprising. There were still many who adhered to the teaching of Galen that the blood follows an ebb and flow movement in the blood vessels. Harvey's work was the result of many careful experiments, but few of his critics took the trouble to repeat the experiments, simply arguing in favour of the older view. His second great book, *Exercitationes de generatione animalium* ("Experiments Concerning Animal Generation"), published in 1651, laid the foundation of modern embryology.

Harvey's discovery of the circulation of the blood was a landmark of medical progress; the new experimental method by which the results were secured was as noteworthy as the work itself. Following the method described by the philosopher Francis Bacon, he drew the truth from experience and not from authority.

There was one gap in Harvey's argument: he was obliged to assume the existence of the capillary vessels that conveyed the blood from the arteries to the veins. This link in the chain of evidence was supplied by Marcello Malpighi of Bologna (who was born in 1628, the year of publication of *De Motu Cordis*). With a primitive microscope Malpighi saw a network of tiny blood vessels in the lung of a frog. Harvey also failed to show why the blood circulated. After Robert Boyle had shown that air is essential to animal life, it was Richard Lower who traced the interaction between air and the blood. Eventually the importance of oxygen, which was confused for a time by some as phlogiston, was revealed, although it was not until the late 18th century that the great chemist Antoine-Laurent Lavoisier discovered the essential nature of oxygen and clarified its relation to respiration.

The microscope

Although the compound microscope had been invented slightly earlier, probably in Holland, its development, like that of the telescope, was the work of Galileo. He was the first to insist upon the value of measurement in science and in medicine, thus replacing theory and guesswork with accuracy. The great Dutch microscopist Antonie van Leeuwenhoek devoted his long life to microscopical studies and was probably the first to see and describe bacteria, reporting his results to the Royal Society of London. In England, Robert Hooke, who was Boyle's assistant and curator to the Royal Society, published his *Micrographia* in 1665, which discussed and illustrated the microscopic structure of a variety of materials.

The futile search for an easy system. Several attempts were made in the 17th century to discover an easy system that would guide the practice of medicine. A substratum of superstition still remained. Richard Wiseman, surgeon to Charles II, affirmed his belief in the "royal touch" as a cure for king's evil, or scrofula, while even the learned English physician Thomas Browne stated that witches really existed. There was, however, a general desire to discard the past and adopt new ideas.

The view of the French philosopher René Descartes that the human body is a machine and that it functions mechanically had its repercussions in medical thought. One group adopting this explanation called themselves the iatrophysicists; another school, preferring to view life as a series of chemical processes, were called iatrochemists. Santorio Santorio, working at Padua, was an early exponent of the iatrophysical view and a pioneer investigator of metabolism. He was especially concerned with the measurement of what he called "insensible perspiration," described in his book *De statica medicina* (1614; "On Medical Measurement"). Another Italian, who developed the idea still further, was Giovanni Alfonso Borelli, a professor of mathematics at Pisa University, who gave his attention to the mechanics and statics of the body and to the physical laws that govern its movements.

The iatrochemical school was founded at Brussels by Jan Baptist van Helmont, whose writings are tinged with the mysticism of the alchemist. A more logical and intelligible view of iatrochemistry was advanced by Franciscus Sylvius, at Leiden; and in England a leading exponent of the same school was Thomas Willis, who is better known for his description of the brain in his *Cerebri anatome nervorumque descriptio et usus* ("Anatomy of the Brain and Descriptions and Functions of the Nerves"), published in 1664 and illustrated by Christopher Wren.

It soon became apparent that no easy road to medical knowledge and practice was to be found along these channels and that the best method was the age-old system of straightforward clinical observation initiated by Hippocrates. The need for a return to these views was strongly urged by Thomas Sydenham, well named "the English Hippocrates." Sydenham was not a voluminous writer and, indeed, had little patience with book learning in medicine; nevertheless he gave excellent descriptions of the phenomena of disease. His greatest service, much needed at the time, was to divert physicians' minds from speculation and lead them back to the bedside, where the true art of medicine could be studied.

Medicine in the 18th century. Even in the 18th century the search for a simple way of healing the sick continued. In Edinburgh the writer and lecturer John Brown expounded his view that there were only two diseases, sthenic (strong) and asthenic (weak), and two treatments, stimulant and sedative; his chief remedies were alcohol and opium. Lively and heated debates took place between his followers, the Brunonians, and the more orthodox Cullenians (followers of William Cullen, a professor of medicine at Glasgow), and the controversy spread to the medical centres of Europe.

At the opposite end of the scale, at least in regard to dosage, was Samuel Hahnemann, of Leipzig, the originator of homeopathy, a system of treatment involving the administration of minute doses of drugs whose effects resemble the effects of the disease being treated. His ideas had a salutary effect upon medical thought at a time when prescriptions were lengthy and doses were large, and his system has had many followers.

By the 18th century the medical school at Leiden had grown to rival that of Padua, and many students were attracted there from abroad. Among them was John Monro, an army surgeon, who resolved that his native city of Edinburgh should have a similar medical school. He specially educated his son Alexander with a view to having him appointed professor of anatomy, and the bold plan was successful. Alexander Monro studied at Leiden under Hermann Boerhaave, the central figure of European medicine and the greatest clinical teacher of his time. Subsequently, three generations of Alexander Monros taught anatomy at Edinburgh University over a continuous period of 126 years. Medical education was increasingly incorporated into the universities of Europe, and Edinburgh became the leading academic centre for medicine in Britain.

Leiden and Edinburgh

In 18th-century London, Scottish doctors were the leaders in surgery and obstetrics. The noted teacher John Hunter conducted extensive researches in comparative anatomy and physiology, founded surgical pathology, and raised surgery to the level of a respectable branch of science. His brother William Hunter, an eminent teacher of anatomy, became famous as an obstetrician. Male doctors were now attending women in childbirth, and the leading obstetrician in London was William Smellie. His well-known *Treatise on the Theory and Practice of Midwifery*, published in three volumes in 1752–64, contained the first systematic discussion on the safe use of obstetrical forceps, which have since saved countless lives. Smellie placed midwifery on a sound scientific footing and helped to establish obstetrics as a recognized medical discipline.

The science of modern pathology also had its beginnings in this century. Giovanni Battista Morgagni, of Padua, in 1761 published his massive work *De sedibus et causis morborum* (*The Seats and Causes of Diseases Investigated*

by Anatomy), a description of the appearances found by postmortem examination of almost 700 cases, in which he attempted to correlate the findings after death with the clinical picture in life.

On the basis of work begun in the 18th century, René Laënnec, a native of Brittany, who practiced medicine in Paris, invented a simple stethoscope, or *cylindre*, as it was originally called. In 1819 he wrote a treatise, *De l'auscultation médiate* ("On Mediate Auscultation"), describing many of the curious sounds in the heart and lungs that are revealed by the instrument. Meanwhile a Viennese physician, Leopold Auenbrugger, discovered another method of investigating diseases of the chest, that of percussion. The son of an innkeeper, he is said to have conceived the idea of tapping with the fingers when he recalled that he had used this method to gauge the level of the fluid contents of his father's casks.

One highly significant medical advance, late in the century, was vaccination. Smallpox, disfiguring and often fatal, was widely prevalent. Inoculation, which had been practiced in the East, was popularized in England in 1721–22 by Lady Mary Wortley Montagu, who is best known for her letters. She observed the practice in Turkey, where it produced a mild form of the disease, thus securing immunity, although not without danger. The next step was taken by Edward Jenner, a country practitioner who had been a pupil of John Hunter. In 1796 Jenner began inoculations with material from cowpox (the bovine form of the disease); and when he later inoculated the same subject with smallpox, the disease did not appear. This procedure—vaccination—has been responsible for eradicating the disease.

Smallpox vaccination

Public health and hygiene were receiving more attention during the 18th century. Population statistics began to be kept, and suggestions arose concerning health legislation. Hospitals were established for a variety of purposes. In Paris, Philippe Pinel initiated bold reforms in the care of the mentally ill, releasing them from their chains and discarding the long-held notion that insanity was caused by demon possession.

Conditions improved for sailors and soldiers as well. James Lind, a British naval surgeon from Edinburgh, recommended fresh fruits and citrus juices to prevent scurvy, a remedy discovered by the Dutch in the 16th century. When the British navy adopted Lind's advice—decades later—this deficiency disease was eliminated. In 1752 a Scotsman, John Pringle, published his classic *Observations on the Diseases of the Army*, which contained numerous recommendations for the health and comfort of the troops. Serving with the British forces during the War of the Austrian Succession, he suggested in 1743 that military hospitals on both sides should be regarded as sanctuaries; this plan eventually led to the establishment of the Red Cross organization in 1864.

Two pseudoscientific doctrines relating to medicine emerged from Vienna in the latter part of the century and attained wide notoriety. Mesmerism, a belief in "animal magnetism" sponsored by Franz Anton Mesmer, probably owed any therapeutic value it had to suggestions given while the patient was under hypnosis. Phrenology, propounded by Franz Joseph Gall, held that the contours of the skull were a guide to an individual's mental faculties and character traits; this theory remained popular throughout the 19th century.

At the same time, sound scientific thinking was making steady progress, and advances in physics, chemistry, and the biological sciences were converging to form a rational scientific basis for every branch of clinical medicine. New knowledge disseminated thoughout Europe and traveled across the sea, where centres of medical excellence were being established in America.

The rise of scientific medicine in the 19th century

The portrayal of the history of medicine becomes more difficult in the 19th century. Discoveries multiply, and the number of eminent doctors is so great that the history is apt to become a series of biographies. Nevertheless, it is possible to discern the leading trends in modern medical thought.

PHYSIOLOGY

By the beginning of the 19th century, the structure of the human body was almost fully known, due to new methods of microscopy and of injections. Even the body's microscopic structure was understood. But as important as anatomical knowledge was an understanding of physiological processes, which were rapidly being elucidated, especially in Germany. There, physiology became established as a distinct science under the guidance of Johannes Müller, who was a professor at Bonn and then at the University of Berlin. An energetic worker and an inspiring teacher, he described his discoveries in a famous textbook, *Handbuch der Physiologie des Menschen* ("Manual of Human Physiology"), published in the 1830s.

The work of Johannes Müller and his students

Among Müller's illustrious pupils were Hermann von Helmholtz, who made significant discoveries relating to sight and hearing and who invented the ophthalmoscope; and Rudolf Virchow, one of the century's great medical scientists, whose outstanding achievement was his conception of the cell as the centre of all pathological changes. Virchow's work *Die Cellularpathologie*, published in 1858, gave the deathblow to the outmoded view that disease is due to an imbalance of the four humours.

In France the most brilliant physiologist of the time was Claude Bernard, whose many important discoveries were the outcome of carefully planned experiments. His researches clarified the role of the pancreas in digestion, revealed the presence of glycogen in the liver, and explained how the contraction and expansion of the blood vessels are controlled by vasomotor nerves. He proposed the concept of the internal environment—the chemical balance in and around the cells—and the importance of its stability. His *Introduction à l'étude de la médecine expérimentale* (1865; *An Introduction to the Study of Experimental Medicine*) is still worthy of study by all who undertake research.

VERIFICATION OF THE GERM THEORY

Perhaps the overarching medical advance of the 19th century, certainly the most spectacular, was the conclusive demonstration that certain diseases, as well as the infection of surgical wounds, were directly caused by minute living organisms. This discovery changed the whole face of pathology and effected a complete revolution in the practice of surgery.

The idea that disease was caused by entry into the body of imperceptible particles was of ancient date. It had been expressed by the Roman encyclopaedist Varro as early as 100 BC, by Fracastoro in 1546, by Athanasius Kircher and Pierre Borel about a century later, and by Francesco Redi, who in 1684 wrote his *Osservazioni intorno agli animali viventi che si trovano negli animali viventi* ("Observations on Living Animals Which Are to Be Found Within Other Living Animals"), in which he sought to disprove the idea of spontaneous generation. Everything must have a parent, he wrote; only life produces life. A 19th-century pioneer in this field, regarded by some as founder of the parasitic theory of infection, was Agostino Bassi of Italy, who showed that a disease of silkworms was caused by a fungus that could be destroyed by chemical agents.

The main credit for establishing the science of bacteriology must be accorded to the French chemist Louis Pasteur. It was Pasteur who, by a brilliant series of experiments, proved that the fermentation of wine and the souring of milk are caused by living microorganisms. His work led to the pasteurization of milk and solved problems of agriculture and industry as well as those of animal and human diseases. He successfully employed inoculations to prevent anthrax in sheep and cattle, chicken cholera in fowl, and finally rabies in humans and dogs. The latter resulted in the widespread establishment of Pasteur institutes.

Influence of Pasteur

From Pasteur, Joseph Lister derived the concepts that enabled him to introduce the antiseptic principle into surgery. In 1865 Lister, a professor of surgery at Glasgow University, began placing an antiseptic barrier of carbolic acid between the wound and the germ-containing atmosphere. Infections and deaths fell dramatically, and his

pioneering work led to more refined techniques of sterilizing the surgical environment.

Obstetrics had already been robbed of some of its terrors by Alexander Gordon at Aberdeen, Scot., Oliver Wendell Holmes at Boston, and Ignaz Semmelweis at Vienna and Pest (Budapest), who advocated disinfection of the hands and clothing of midwives and medical students who attended confinements. These measures produced a marked reduction in cases of puerperal fever, the bacterial scourge of women following childbirth.

Another pioneer in bacteriology was the German physician Robert Koch, who showed how bacteria could be cultivated, isolated, and examined in the laboratory. A meticulous investigator, Koch discovered the organisms of tuberculosis, in 1882, and cholera, in 1883. By the end of the century many other disease-producing microorganisms had been identified.

DISCOVERIES IN CLINICAL MEDICINE AND ANESTHESIA

There was perhaps some danger that in the search for bacteria other causes of disease would escape detection. Many physicians, however, were working along different lines in the 19th century. Among them were a group attached to Guy's Hospital, in London: Richard Bright, Thomas Addison, and Sir William Gull. Bright contributed significantly to the knowledge of kidney diseases, including Bright's disease, and Addison gave his name to disorders of the adrenal glands and the blood. Gull, a famous clinical teacher, left a legacy of pithy aphorisms that might well rank with those of Hippocrates.

The 19th century

In Dublin Robert Graves and William Stokes introduced new methods in clinical diagnosis and medical training; while in Paris a leading clinician, Pierre-Charles-Alexandre Louis, was attracting many students from America by the excellence of his teaching. By the early 19th century the United States was ready to send back the results of its own researches and breakthroughs. In 1809, in a small Kentucky town, Ephraim McDowell boldly operated on a woman—without anesthesia or antisepsis—and successfully removed a large ovarian tumour. William Beaumont, in treating a shotgun wound of the stomach, was led to make many original observations that were published in 1833 as *Experiments and Observations on the Gastric Juice and the Physiology of Digestion.*

The most famous contribution by the United States to medical progress at this period was undoubtedly the introduction of general anesthesia, a procedure that not only liberated the patient from the fearful pain of surgery but also enabled the surgeon to perform more extensive operations. The discovery was marred by controversy. Crawford Long, Gardner Colton, Horace Wells, and Charles Jackson are all claimants for priority; some used nitrous oxide gas, and others employed ether, which was less capricious. There is little doubt, however, that it was William Thomas Morton who, on Oct. 16, 1846, at Massachusetts General Hospital, in Boston, first demonstrated before a gathering of physicians the use of ether as a general anesthetic. The news quickly reached Europe, and general anesthesia soon became prevalent in surgery. At Edinburgh, the professor of midwifery, James Young Simpson, had been experimenting upon himself and his assistants, inhaling various vapours with the object of discovering an effective anesthetic. In November 1847 chloroform was tried with complete success, and soon it was preferred to ether and became the anesthetic of choice.

ADVANCES AT THE END OF THE CENTURY

While antisepsis and anesthesia placed surgery on an entirely new footing, similarly important work was carried out in other fields of study, such as parasitology and disease transmission. Patrick Manson, a British pioneer in tropical medicine, showed in China, in 1877, how insects can carry disease and how the embryos of the *Filaria* worm, which can cause elephantiasis, are transmitted by the mosquito. Manson explained his views to a British army surgeon, Ronald Ross, then working on the problem of malaria, and Ross discovered the malarial parasite in the stomach of the *Anopheles* mosquito in 1897.

Insect transmission of disease

In Cuba, Carlos Finlay expressed the view, in 1881, that yellow fever is carried by the *Stegomyia* mosquito. Following his lead, the Americans Walter Reed, William Gorgas, and others were able to conquer the scourge of yellow fever in Panama and made possible the completion of the Panama Canal by reducing the death rate there from 176 per 1,000 to 6 per 1,000.

Other victories in preventive medicine ensued, because the maintenance of health was now becoming as important a concern as the cure of disease; and the 20th century was to witness the evolution and progress of national health services in a number of countries. In addition, spectacular advances in diagnosis and treatment followed the discovery of X rays by Wilhelm Conrad Röntgen, in 1895, and of radium by Pierre and Marie Curie in 1898. Before the turn of the century, too, the vast new field of psychiatry had been opened up by Sigmund Freud. The tremendous increase in scientific knowledge during the 19th century radically altered and expanded the practice of medicine. Concern for upholding the quality of services led to the establishment of public and professional bodies to govern the standards for medical training and practice.

Medicine in the 20th century

The 20th century has produced such a plethora of discoveries and advances that in some ways the face of medicine has changed out of all recognition. In 1901, for instance, in the United Kingdom the expectation of life at birth, a primary indicator of the effect of health care on mortality (but also reflecting the state of health education, housing, and nutrition), was 48 years for males and 51.6 years for females. After steady increases, by the 1980s life expectancy had reached 71.4 years for males and 77.2 years for females. Other industrialized nations showed similar dramatic increases. Indeed, the outlook has so altered that, with the exception of diseases such as cancer and AIDS, attention has become focused on morbidity rather than mortality, and the emphasis has changed from keeping people alive to keeping them fit.

The rapid progress of medicine in this era was reinforced by enormous improvements in communication between scientists throughout the world. Through publications, conferences, and—later—computers and electronic media, they freely exchanged ideas and reported on their endeavours. No longer was it common for an individual to work in isolation. Although specialization increased, teamwork became the norm. It consequently has become more difficult to ascribe medical accomplishments to particular individuals.

In the first half of the century, emphasis continued to be placed on combating infection, and notable landmarks were also attained in endocrinology, nutrition, and other areas. In the years following World War II, insights derived from cell biology altered basic concepts of the disease process; new discoveries in biochemistry and physiology opened the way for more precise diagnostic tests and more effective therapies; and spectacular advances in biomedical engineering enabled the physician and surgeon to probe into the structures and functions of the body by noninvasive imaging techniques like ultrasound (sonar), computerized axial tomography (CAT), and nuclear magnetic resonance (NMR). With each new scientific development, medical practices of just a few years earlier became obsolete.

INFECTIOUS DISEASES AND CHEMOTHERAPY

In the years following the turn of the century, ongoing research concentrated on the nature of infectious diseases and their means of transmission. Increasing numbers of pathogenic organisms were discovered and classified. Some, such as the rickettsias, which cause diseases like typhus, were smaller than bacteria; some were larger, such as the protozoans that engender malaria and other tropical diseases. The smallest to be identified were the viruses, producers of many diseases, among them mumps, measles, German measles, and poliomyelitis; and in 1910 Peyton Rous showed that a virus could also cause a malignant tumour, a sarcoma in chickens.

Varieties of microorganisms

There was still little to be done for the victims of most infectious organisms beyond drainage, poultices, and ointments, in the case of local infections, and rest and nourishment for severe diseases. The search for treatments aimed at both vaccines and chemical remedies.

Ehrlich and arsphenamine. Germany was well to the forefront in medical progress. The scientific approach to medicine had been developed there long before it spread to other countries, and postgraduates flocked to German medical schools from all over the world. The opening decade of the 20th century has been well described as the golden age of German medicine. Outstanding among its leaders was Paul Ehrlich.

While still a student, Ehrlich carried out some work on lead poisoning from which he evolved the theory that was to guide much of his subsequent work—that certain tissues have a selective affinity for certain chemicals. He experimented with the effects of various chemical substances on disease organisms. In 1910, with his colleague Sahachiro Hata, he conducted tests on arsphenamine, once sold under the commercial name Salvarsan. Their success inaugurated the chemotherapeutic era, which was to revolutionize the treatment and control of infectious diseases. Salvarsan, a synthetic preparation containing arsenic, is lethal to the microorganism responsible for syphilis. Until the introduction of penicillin, Salvarsan or one of its modifications remained the standard treatment of syphilis and went far toward bringing this social and medical scourge under control.

Sulfonamide drugs. In 1932 the German bacteriologist Gerhard Domagk announced that the red dye Prontosil is active against streptococcal infections in mice and humans. Soon afterward French workers showed that its active antibacterial agent is sulfanilamide. In 1936 the English physician Leonard Colebrook and his colleagues provided overwhelming evidence of the efficacy of both Prontosil and sulfanilamide in streptococcal septicemia (bloodstream infection), thereby ushering in the sulfonamide era. New sulfonamides, which appeared with astonishing rapidity, had greater potency, wider antibacterial range, or lower toxicity. Some stood the test of time; others, like the original sulfanilamide and its immediate successor, sulfapyridine, were replaced by safer and more powerful successors.

Antibiotics. *Penicillin.* A dramatic episode in medical history occurred in 1928, when Alexander Fleming noticed the inhibitory action of a stray mold on a plate culture of staphylococcus bacteria in his laboratory at St. Mary's Hospital, London. Many other bacteriologists must have made the observation, but none had realized the possible implications. The mold was a strain of *Penicillium—P. notatum*—which gave its name to the now-famous drug penicillin. In spite of his conviction that penicillin was a potent antibacterial agent, Fleming was unable to carry his work to fruition, mainly because biochemists at the time were unable to isolate it in sufficient quantities or in a sufficiently pure form to allow its use on patients.

Ten years later Howard Florey, Ernst Chain, and their colleagues at Oxford University took up the problem again They isolated penicillin in a form that was fairly pure (by standards then current) and demonstrated its potency and relative lack of toxicity. By then World War II had begun, and techniques to facilitate commercial production were developed in the United States. By 1944 adequate amounts were available to meet the extraordinary needs of wartime.

Antituberculous drugs. While penicillin is the most useful and the safest antibiotic, it suffers from certain disadvantages. The most important of these is that it is not active against *Mycobacterium tuberculosis,* the bacillus of tuberculosis. In view of the importance of tuberculosis as a public health hazard, this is a serious defect. The position was rapidly rectified when, in 1944, Selman A. Waksman and his colleagues announced the discovery of streptomycin from cultures of a soil organism, *Streptomyces griseus,* and stated that it was active against *M. tuberculosis.* Subsequent clinical trials amply confirmed this claim. Streptomycin suffers, however, from the great disadvantage that the tubercle bacillus tends to become resistant to it. Fortunately, other drugs became available to supplement it, the two most important being para-aminosalicylic acid (or PAS) and isoniazid. With a combination of two or more of these preparations, the outlook in tuberculosis improved immeasurably. The disease was not conquered, but it was brought well under control.

Streptomycin, PAS, and isoniazid

Other antibiotics. Penicillin is not effective over the entire field of microorganisms pathogenic to humans. During the 1950s the search for antibiotics to fill this gap resulted in a steady stream of them, some with a much wider antibacterial range than penicillin (the so-called broad-spectrum antibiotics) and some capable of coping with those microorganisms that are inherently resistant to penicillin or that have developed resistance through exposure to penicillin.

This tendency of microorganisms to develop resistance to penicillin at one time threatened to become almost as serious a problem as the development of resistance to streptomycin by the bacillus of tuberculosis. Fortunately, early appreciation of the problem by clinicians resulted in more discriminate use of penicillin. Scientists continued to look for means of obtaining new varieties of penicillin, and their researches produced the so-called semisynthetic antibiotics, some of which are active when taken by mouth, while others are effective against microorganisms that have developed resistance to the earlier form of penicillin.

IMMUNOLOGY

Dramatic though they undoubtedly were, the advances in chemotherapy still left one important area vulnerable, that of the viruses. It was in bringing viruses under control that advances in immunology—the study of immunity—played such a striking part. One of the paradoxes of medicine is that the first large-scale immunization against a viral disease was instituted and established long before viruses were discovered. When Edward Jenner introduced vaccination against the virus that causes smallpox, the identification of viruses was still 100 years in the future. It took almost another half century to discover an effective method of producing antiviral vaccines that were both safe and effective.

In the meantime, however, the process by which the body reacts against infectious organisms to generate immunity became better understood. In Paris, Élie Metchnikoff had already detected the role of white blood cells in the immune reaction, and Jules Bordet had identified antibodies in the blood serum. The mechanisms of antibody activity were used to devise diagnostic tests for a number of diseases. In 1906 August von Wassermann gave his name to the blood test for syphilis, and in 1908 the tuberculin test—the skin test for tuberculosis—came into use. At the same time, methods of producing effective substances for inoculation were improved, and immunization against bacterial diseases made rapid progress.

Wassermann and the tuberculin test

Antibacterial vaccination. *Typhoid.* In 1897 the English bacteriologist Almroth Wright introduced a vaccine prepared from killed typhoid bacilli as a preventive of typhoid. Preliminary trials in the Indian army produced excellent results, and typhoid vaccination was adopted for the use of British troops serving in the South African War. Unfortunately, the method of administration was inadequately controlled, and the government sanctioned inoculations only for soldiers that "voluntarily presented themselves for this purpose prior to their embarkation for the seat of war." The result was that, according to the official records, only 14,626 men volunteered out of a total strength of 328,244 who served during the three years of the war. Although later analysis showed that inoculation had had a beneficial effect, there were 57,684 cases of typhoid—approximately one in six of the British troops engaged—with 9,022 deaths.

A bitter controversy over the merits of the vaccine followed, but before the outbreak of World War I immunization had been officially adopted by the army. Comparative statistics would seem to provide striking confirmation of the value of antityphoid inoculation, even allowing for the better sanitary arrangements in the latter war. In the South African War the annual incidence of enteric infections (typhoid and paratyphoid) was 105 per 1,000 troops, and the annual death rate was 14.6 per 1,000; the comparable

figures for World War I were 2.35 and 0.139, respectively.

It is perhaps a sign of the increasingly critical outlook that developed in medicine in the post-1945 era that experts continued to differ on some aspects of typhoid immunization. There was no question as to its fundamental efficacy, but there was considerable variation of opinion as to the best vaccine to use and the most effective way of administering it. Moreover, it was often difficult to decide to what extent the decline in typhoid was attributable to improved sanitary conditions and what to the greater use of the vaccine.

Tetanus. The other great hazard of war that was brought under control in World War I was tetanus. This was achieved by the prophylactic injection of tetanus antitoxin into all wounded men. The serum was originally prepared by the bacteriologists Emil von Behring and Shibasaburo Kitasato in 1890–92, and the results of this first large-scale trial amply confirmed its efficacy. (Tetanus antitoxin is a sterile solution of antibody globulins—a type of blood protein—from immunized horses or cattle.)

It was not until the 1930s, however, that an efficient vaccine, or toxoid, as it is known in the cases of tetanus and diphtheria, was produced against tetanus. (Tetanus toxoid is a preparation of the toxin—or poison—produced by the microorganism; injected into humans, it stimulates the body's own defenses against the disease, thus bringing about immunity.) Again, a war was to provide the opportunity for testing on a large scale, and experience with tetanus toxoid in World War II indicated that it gave a high degree of protection.

Diphtheria. The story of diphtheria is comparable to that of tetanus, though even more dramatic. First, as with tetanus antitoxin, came the preparation of diphtheria antitoxin by Behring and Kitasato in 1890. As the antitoxin came into general use for the treatment of cases, the death rate began to decline. There was no significant fall in the number of cases, however, until a toxin–antitoxin mixture, introduced by Behring in 1913, was used to immunize children. A more effective toxoid was introduced by the French bacteriologist Gaston Ramon in 1923, and with subsequent improvements this became one of the most effective vaccines available in medicine. Where mass immunization of children with the toxoid was practiced, as in the United States and Canada beginning in the late 1930s and in England and Wales in the early 1940s, cases of diphtheria and deaths from the disease became almost nonexistent. In England and Wales, for instance, the number of deaths fell from an annual average of 1,830 in 1940–44 to zero in 1969. Administration of a combined vaccine against diphtheria, pertussis (whooping cough), and tetanus (DPT) is recommended for young children. Although an increasing number of dangerous side effects from the DPT vaccine have been reported, it continues to be used in most countries because of the protection it affords.

Mass diphtheria immunization of children

BCG vaccine for tuberculosis. If, as is universally accepted, prevention is better than cure, immunization is the ideal way of dealing with diseases caused by microorganisms. An effective, safe vaccine protects the individual from disease, whereas chemotherapy merely copes with the infection once the individual has been affected. In spite of its undoubted value, however, immunization has been a recurring source of dispute. Like vaccination against typhoid (and against poliomyelitis later), tuberculosis immunization evoked widespread contention.

In 1908 Albert Calmette, a pupil of Pasteur, and Camille Guérin produced an avirulent (weakened) strain of the tubercle bacillus. About 13 years later, vaccination of children against tuberculosis was introduced, with a vaccine made from this avirulent strain and known as BCG (bacillus Calmette-Guérin) vaccine. Although it was adopted in France, Scandinavia, and elsewhere, British and U.S. authorities frowned upon its use on the grounds that it was not safe and that the statistical evidence in its favour was not convincing.

One of the stumbling blocks in the way of its widespread adoption was what came to be known as the Lübeck disaster. In the spring of 1930, 249 infants were vaccinated with BCG vaccine in Lübeck, Ger.; by autumn, 73 of the 249 were dead. Criminal proceedings were instituted against those responsible for giving the vaccine. The final verdict was that the vaccine had been contaminated, and the BCG vaccine itself was exonerated from any responsibility for the deaths. A bitter controversy followed, but in the end the protagonists of the vaccine won when a further trial showed that the vaccine was safe and that it protected four out of five of those vaccinated.

Immunization against viral diseases. With the exception of smallpox, it was not until well into the 20th century that efficient viral vaccines became available. In fact, it was not until the 1930s that much began to be known about viruses. The two developments that contributed most to the rapid growth in knowledge after that time were the introduction of tissue culture as a means of growing viruses in the laboratory and the availability of the electron microscope. Once the virus could be cultivated with comparative ease in the laboratory, the research worker could study it with care and evolve methods for producing one of the two requirements for a safe and effective vaccine: either a virus that was so attenuated, or weakened, that it could not produce the disease for which it was responsible in its normally virulent form; or a killed virus that retained the faculty of inducing a protective antibody response in the vaccinated individual.

The first of the viral vaccines to result from these advances was for yellow fever, developed by the microbiologist Max Theiler in the late 1930s. About 1945 the first relatively effective vaccine was produced for influenza; in 1954 the American physician Jonas E. Salk introduced a vaccine for poliomyelitis; and in 1960 an oral poliomyelitis vaccine, developed by the virologist Albert B. Sabin, came into wide use.

Poliomyelitis vaccine

These vaccines went far toward bringing under control three of the major diseases of the time although, in the case of influenza, a major complication is the disturbing proclivity of the virus to change its character from one epidemic to another. Even so, sufficient progress has been made to ensure that a pandemic like the one that swept the world in 1918–19, killing more than 15,000,000 people, is unlikely to occur again. Centres are now equipped to monitor outbreaks of influenza throughout the world in order to establish the identity of the responsible viruses and, if necessary, take steps to produce appropriate vaccines.

During the 1960s effective vaccines came into use for measles and rubella (German measles). Both evoked a certain amount of controversy. In the case of measles in the Western world it was contended that, if acquired in childhood, it is not a particularly hazardous malady, and the naturally acquired disease evokes permanent immunity in the vast majority of cases. Conversely, the vaccine induces a certain number of adverse reactions, and the duration of the immunity it produces is problematical. In the end the official view was that universal measles vaccination is to be commended.

The situation with rubella vaccination was different. This is a fundamentally mild affliction, and the only cause for anxiety is its proclivity to induce congenital deformities if a pregnant woman should acquire the disease. Once an effective vaccine was available, the problem was the extent to which it should be used. Ultimately the consensus was reached that all girls who had not already had the disease should be vaccinated at about 12 years. In the United States children are routinely immunized against measles, mumps, and rubella at the age of 15 months.

The immune response. With advances in cell biology in the second half of the 20th century came a more profound understanding of both normal and abnormal conditions in the body. Electron microscopy enabled observers to peer more deeply into the structures of the cell, and chemical investigations revealed clues to their functions in the cell's intricate metabolism. The overriding importance of the nuclear genetic material DNA (deoxyribonucleic acid) in regulating the cell's protein and enzyme production lines became evident. A clearer comprehension also emerged of the ways in which the cells of the body defend themselves by modifying their chemical activities to produce antibodies against injurious agents.

Understanding the cell

Up until the turn of the century, immunity referred

mostly to the means of resistance of an animal to invasion by a parasite or microorganism. Around mid-century there arose a growing realization that immunity and immunology cover a much wider field and are concerned with mechanisms for preserving the integrity of the individual. The introduction of organ transplantation, with its dreaded complication of tissue rejection, brought this broader concept of immunology to the fore.

At the same time, research workers and clinicians began to appreciate the far-reaching implications of immunity in relation to endocrinology, genetics, tumour biology, and the biology of a number of other maladies. The so-called autoimmune diseases are caused by an aberrant series of immune responses by which the body's own cells are attacked. Suspicion is growing that a number of major disorders such as diabetes, rheumatoid arthritis, and multiple sclerosis may be caused by similar mechanisms.

In some conditions viruses invade the genetic material of cells and distort their metabolic processes. Such viruses may lie dormant for many years before becoming active. This may be the underlying cause of many cancers, in which cells escape from the usual constraints imposed upon them by the normal body. The dreaded affliction of acquired immune deficiency syndrome (AIDS) is caused by a virus that has a long dormant period and then attacks the cells that produce antibodies. The result is that the affected person is not able to generate an immune response to infections or malignancies.

ENDOCRINOLOGY

At the beginning of the 20th century, endocrinology was in its infancy. Indeed, it was not until 1905 that Ernest H. Starling, one of the many brilliant pupils of Edward Sharpey-Schafer, the dean of British physiology during the early decades of the century, introduced the term hormone for the internal secretions of the endocrine glands. In 1891 the English physician George Redmayne Murray achieved the first success in treating myxedema (the common form of hypothyroidism) with an extract of the thyroid gland. Three years later, Sharpey-Schafer and George Oliver demonstrated in extracts of the adrenal glands a substance that raised the blood pressure; and in 1901 Jokichi Takamine, a Japanese chemist working in the United States, isolated this active principle, known as epinephrine or adrenaline.

Insulin. During the first two decades of the century, steady progress was made in the isolation, identification, and study of the active principles of the various endocrine glands, but the outstanding event of the early years was the discovery of insulin by Frederick Banting, Charles H. Best, and J.J.R. Macleod in 1921. Almost overnight the lot of the diabetic patient changed from a sentence of almost certain death to a prospect not only of survival but of a long and healthy life.

For more than 30 years, some of the greatest minds in physiology had been seeking the cause of diabetes mellitus. In 1889 the German physicians Joseph von Mering and Oskar Minkowski had shown that removal of the pancreas in dogs produced the disease. In 1901 the American pathologist Eugene L. Opie described degenerative changes in the clumps of cells in the pancreas known as the islets of Langerhans, thus confirming the association between failure in the function of these cells and diabetes. Sharpey-Schafer concluded that the islets of Langerhans secrete a substance that controls the metabolism of carbohydrate. Then Banting, Best, and Macleod, working at the University of Toronto, succeeded in isolating the elusive hormone and gave it the name insulin.

Insulin was available in a variety of forms, but synthesis on a commercial scale was not achieved, and the only source of the hormone was the pancreas of animals. One of its practical disadvantages is that it has to be given by injection; consequently an intense search was conducted for some alternative substance that would be active when taken by mouth. Various preparations—oral hypoglycemic agents, as they are known—appeared that were effective to a certain extent in controlling diabetes, but evidence indicated that these were only of value in relatively mild cases of the disease. For the person with advanced diabetes, a normal, healthy life remained dependent upon the continuing use of insulin injections.

Cortisone. Another major advance in endocrinology came from the Mayo Clinic, in Rochester, Minn. In 1949 Philip S. Hench and his colleagues announced that a substance isolated from the cortex of the adrenal gland had a dramatic effect upon rheumatoid arthritis. This was compound E, or cortisone, as it came to be known, which had been isolated by Edward C. Kendall in 1935. Cortisone and its many derivatives proved to be potent as anti-inflammatory agents. Although it is not a cure for rheumatoid arthritis, as a temporary measure cortisone can often control the acute exacerbation caused by the disease and can provide relief in other conditions, such as acute rheumatic fever, certain kidney diseases, certain serious diseases of the skin, and some allergic conditions, including acute exacerbations of asthma. Of even more long-term importance is the valuable role it has as a research tool.

Sex hormones. Not the least of the advances in endocrinology was the increasing knowledge and understanding of the sex hormones. This culminated in the application of this knowledge to the problem of birth control. After an initial stage of hesitancy, the contraceptive pill, with its basic rationale of preventing ovulation, was accepted by the vast majority of family-planning organizations and many gynecologists as the most satisfactory method of contraception. Its risks, practical and theoretical, introduced a note of caution, but this was not sufficient to detract from the wide appeal induced by its effectiveness and ease of use.

VITAMINS

In the field of nutrition, the outstanding advance of the 20th century was the discovery and the appreciation of the importance to health of the "accessory food factors," or vitamins. Various workers had shown that animals did not thrive on a synthetic diet containing all the correct amounts of protein, fat, and carbohydrate; they even suggested that there must be some unknown ingredients in natural food that were essential for growth and the maintenance of health. But little progress was made in this field until the classical experiments of the English biologist F. Gowland Hopkins were published in 1912. These were so conclusive that there could be no doubt that what he termed "accessory substances" were essential for health and growth.

The name vitamine was suggested for these substances by the biochemist Casimir Funk in the belief that they were amines, certain compounds derived from ammonia. In due course, when it was realized that they were not amines, the term was altered to vitamin.

Once the concept of vitamins was established on a firm scientific basis it was not long before their identity began to be revealed. Soon there was a long series of vitamins, best known by the letters of the alphabet after which they were originally named when their chemical identity was still unknown. By supplementing the diet with foods containing particular vitamins, deficiency diseases such as rickets (due to deficiency of vitamin D) and scurvy (due to lack of vitamin C, or ascorbic acid) practically disappeared from Western countries, while deficiency diseases such as beriberi (caused by lack of vitamin B_1, or thiamine), which were endemic in Eastern countries, either disappeared or could be remedied with the greatest of ease.

The isolation of vitamin B_{12}, or cyanocobalamin, was of particular interest because it almost rounded off the fascinating story of how pernicious anemia was brought under control. Throughout the first two decades of the century, the diagnosis of pernicious anemia, like that of diabetes mellitus, was nearly equivalent to a death sentence. Unlike the more common form of so-called secondary anemia, it did not respond to the administration of suitable iron salts, and no other form of treatment touched it; hence, the grimly appropriate title of pernicious anemia.

In the early 1920s, George R. Minot, one of the many brilliant investigators that Harvard University has contributed to medical research, became interested in work being done by the American pathologist George H. Whip-

ple on the beneficial effects of raw beef liver in severe experimental anemia. With a Harvard colleague, William P. Murphy, he decided to investigate the effect of raw liver in patients with pernicious anemia, and in 1926 they were able to announce that this form of therapy was successful. The validity of their findings was amply confirmed, and the fear of pernicious anemia came to an end.

Liver therapy in pernicious anemia

As so often happens in medicine, many years were to pass before the rationale of liver therapy in pernicious anemia was fully understood. In 1948, however, almost simultaneously in the United States and Britain, the active principle, cyanocobalamin, was isolated from liver, and this vitamin became the standard treatment for pernicious anemia.

MALIGNANT DISEASE

While progress was the hallmark of medicine after the beginning of the 20th century, there is one field in which a gloomier picture must be painted, that of malignant disease, or cancer. It is the second most common cause of death in most Western countries in the second half of the 20th century, being exceeded only by deaths from heart disease. Some progress, however, has been achieved. The causes of the various types of malignancies are not known, but many more methods are available for attacking the problem; surgery remains the principal therapeutic standby, but radiotherapy and chemotherapy are increasingly used.

Soon after the discovery of radium was announced, in 1898, its potentialities in treating cancer were realized; in due course it assumed an important role in therapy. Simultaneously, deep X-ray therapy was developed, and with the atomic age came the use of radioactive isotopes. (A radioactive isotope is an unstable variant of a substance that has a stable form; during the process of breaking down, the unstable form emits radiation.) High-voltage X-ray therapy and radioactive isotopes have largely replaced radium. Whereas irradiation long depended upon X rays generated at 250 kilovolts, machines that are capable of producing X rays generated at 8,000 kilovolts and betatrons of up to 22,000,000 electron volts (MeV) have come into clinical use.

The most effective of the isotopes is radioactive cobalt. Telecobalt machines (those that hold the cobalt at a distance from the body) are available containing 2,000 curies or more of the isotope, an amount equivalent to 3,000 grams of radium and sending out a beam equivalent to that from a 3,000-kilovolt X-ray machine.

Chemotherapy for cancer

Of even more significance have been the developments in the chemotherapy of cancer. Nothing remotely resembling a chemotherapeutic cure has been achieved, but in certain forms of malignant disease, such as leukemia, which cannot be treated by surgery, palliative effects have been achieved that prolong life and allow the patient in many instances to lead a comparatively normal existence.

Fundamentally, however, perhaps the most important advance of all in this field has been the increasing appreciation of the importance of prevention. The discovery of the relationship between cigarette smoking and lung cancer is the classic example. Less publicized, but of equal import, is the continuing supervision of new techniques in industry and food manufacture in an attempt to ensure that they do not involve the use of cancer-causing substances.

TROPICAL MEDICINE

The first half of the 20th century witnessed the virtual conquest of three of the major diseases of the tropics: malaria, yellow fever, and leprosy. At the turn of the century, as for the preceding two centuries, quinine was the only known drug to have any appreciable effect on malaria. With the increasing development of tropical countries and rising standards of public health, it became obvious that quinine was not completely satisfactory. Intensive research between World Wars I and II indicated that several synthetic compounds were more effective. The first of these to become available, in 1934, was quinacrine (known as mepacrine, Atabrine, or Atebrin). In World War II it amply fulfilled the highest expectations and helped to reduce disease among Allied troops in Africa, Southeast Asia, and the Far East. A number of other effective antimalarial drugs subsequently became available.

An even brighter prospect—the virtual eradication of malaria—was opened up by the introduction, during World War II, of the insecticide DDT (1,1,1-trichloro-2,2,-bis[*p*-chlorophenyl]ethane, or dichlorodiphenyltrichloroethane). It had long been realized that the only effective way of controlling malaria was to eradicate the anopheline mosquitoes that transmit the disease. Older methods of mosquito control, however, were cumbersome and expensive. The lethal effect of DDT on the mosquito, its relative cheapness, and its ease of use on a widespread scale provided the answer. An intensive worldwide campaign, sponsored by the World Health Organization, was planned and went far toward bringing malaria under control.

The major problem encountered with respect to effectiveness was that the mosquitoes were able to develop a resistance to DDT; but the introduction of other insecticides, such as dieldrin and lindane (BHC), helped to overcome this difficulty. In recent years the use of these and other insecticides has been strongly criticized by ecologists, however.

Yellow fever is another mosquito-transmitted disease, and the prophylactic value of modern insecticides in its control was almost as great as in the case of malaria. The forest reservoirs of the virus present a more difficult problem, but the combined use of immunization and insecticides did much to bring this disease under control.

Until the 1940s the only drugs available for treating leprosy were the chaulmoogra oils and their derivatives. These, though helpful, were far from satisfactory. In the 1940s the group of drugs known as the sulfones appeared, and it soon became apparent that they were infinitely better than any other group of drugs in the treatment of leprosy. Several other drugs later proved promising. Although there is as yet no known cure—in the strict sense of the term—for leprosy, the outlook has so changed that there are good grounds for believing that this age-old scourge can be brought under control and the victims of the disease saved from those dreaded mutilations that have given leprosy such a fearsome reputation throughout the ages. Surgery in the 20th century

THE OPENING PHASE

Three seemingly insuperable obstacles beset the surgeon in the years before the mid-19th century: pain, infection, and shock. Once these were overcome, the surgeon believed that he could burst the bonds of centuries and become the master of his craft. There is more, however, to anesthesia than putting the patient to sleep. Infection, despite first antisepsis (destruction of microorganisms present) and later asepsis (avoidance of contamination), is still an ever-present menace; and shock continues to perplex physicians. But in the 20th century, surgery has progressed farther, faster, and more dramatically than in all preceding ages.

The situation encountered. The shape of surgery that entered the new century was clearly recognizable as the forerunner of today's, blurred and hazy though the outlines may now seem. The operating theatre still retained an aura of the past, when the surgeon played to his audience and the patient was little more than a stage prop. In most hospitals it was a high room lit by a skylight, with tiers of benches rising above the narrow, wooden operating table. The instruments, kept in glazed or wooden cupboards around the walls, were of forged steel, unplated, and with handles of wood or ivory.

The means to combat infection hovered between antisepsis and asepsis. Instruments and dressings were mostly sterilized by soaking them in dilute carbolic acid (or other antiseptic), and the surgeon often endured a gown freshly wrung out in the same solution. Asepsis gained ground fast, however. It had been born in the Berlin clinic of Ernst von Bergmann where, in 1886, steam sterilization had been introduced. Gradually, this led to the complete aseptic ritual, which has as its basis the bacterial cleanliness (as opposed to social cleanliness) of everything that

comes in contact with the wound. Hermann Kümmell, of Hamburg, devised the routine of "scrubbing up." In 1890 William Stewart Halsted, of Johns Hopkins University, had rubber gloves specially made for operating, and in 1896 Johannes von Mikulicz-Radecki, a Pole working at Breslau, Ger., invented the gauze mask.

Many surgeons, brought up in a confused misunderstanding of the antiseptic principle—believing that carbolic would cover a multitude of sins, many of which they were ignorant of committing—failed to grasp what asepsis was all about. Thomas Annandale, for example, blew through his catheters to make sure that they were clear, and many an instrument, dropped accidentally, was simply given a quick wipe and returned to use. Tradition died hard, and asepsis had an uphill struggle before it was fully accepted. "I believe firmly that more patients have died from the use of gloves than have ever been saved from infection by their use," wrote W.P. Carr, an American, in 1911. Over the years, however, a sound technique was evolved as the foundation for the growth of modern surgery.

Anesthesia at the turn of the century

Anesthesia, at the turn of the century, progressed slowly. Few physicians made a career of the subject, and frequently the patient was rendered unconscious by a student, a nurse, or a porter wielding a rag and bottle. Chloroform was overwhelmingly more popular than ether, on account of its ease of administration, despite the fact that it was liable to kill by stopping the heart.

Although by the end of the first decade, nitrous oxide (laughing gas) combined with ether had displaced—but by no means entirely—the use of chloroform, the surgical problems were far from ended. For years to come the abdominal surgeon besought the anesthetist to deepen the level of anesthesia and thus relax the abdominal muscles; the anesthetist responded to the best of his ability, acutely aware that the deeper he went, the closer the patient was to death. When other anesthetic agents were discovered, the anesthetist came into his own, and many advances in spheres such as brain and heart surgery would have been impossible without his skill.

The third obstacle, shock, is perhaps the most complex and the most difficult to define satisfactorily. The only major cause properly appreciated at the start of the 20th century was loss of blood, and once that had occurred nothing, in those days, could be done. And so, the study of shock—its causes, its effects on human physiology, and its prevention and treatment—became all-important to the progress of surgery.

In the latter part of the 19th century, then, surgeons had been liberated from the age-old bogies of pain, pus, and hospital gangrene. Hitherto, operations had been restricted to amputations, cutting for stone in the bladder, tying off arterial aneurysms (bulging and thinning of artery walls), repairing hernias, and a variety of procedures that could be done without going too deeply beneath the skin. But the anatomical knowledge, a crude skill derived from practice on dead bodies, and above all the enthusiasm, were there waiting. Largely ignoring the mass of problems they uncovered, surgeons launched forth into an exploration of the human body.

They acquired a reputation for showmanship; but much of their surgery, though speedy and spectacular, was rough and ready. There were a few who developed supreme skill and dexterity and could have undertaken a modern operation with but little practice; indeed, some devised the very operations still in use today. One such was Theodor Billroth, head of the surgical clinic at Vienna, who collected a formidable list of successful "first" operations. He represented the best of his generation—a surgical genius, an accomplished musician, and a kind, gentle man who brought the breath of humanity to his work. Moreover, the men he trained, including von Mikulicz, Vincenz Czerny, and Anton von Eiselsberg, consolidated the brilliant start that he had given to abdominal surgery in Europe.

Billroth's influence

Changes before World War I. The opening decade of the 20th century was a period of transition. Flamboyant exhibitionism was falling from favour as surgeons, through experience, learned the merits of painstaking, conscientious operation—treating the tissues gently and carefully controlling every bleeding point. The individualist was not submerged, however, and for many years the development of the various branches of surgery rested on the shoulders of a few clearly identifiable men. Teamwork on a large scale arrived only after World War II. The surgeon, at first, was undisputed master in his own wards and theatre. But as time went on and he found he could not solve his problems alone, he called for help from specialists in other fields of medicine and, even more significantly, from his colleagues in other scientific disciplines.

The increasing scope of surgery led to specialization. Admittedly, most general surgeons had a special interest, and for a long time there had been an element of specialization in such fields as ophthalmology, orthopedics, obstetrics, and gynecology; but before long it became apparent that, to achieve progress in certain areas, surgeons had to concentrate their attention on that particular subject.

Abdominal surgery. By the start of the 20th century, abdominal surgery, which provided the general surgeon with the bulk of his work, had grown beyond infancy, thanks largely to Billroth. In 1881 he had performed the first successful removal of part of the stomach for cancer. His next two cases were failures, and he was stoned in the streets of Vienna. Yet, he persisted and by 1891 had carried out 41 more of these operations with 16 deaths—a remarkable achievement for that era.

Peptic ulcers (gastric and duodenal) appeared on the surgical scene (perhaps as a new disease, but more probably because they had not been diagnosed previously), and in 1881 Ludwig Rydygier cured a young woman of her gastric ulcer by removing it. Bypass operations—gastroenterostomies—soon became more popular, however, and enjoyed a vogue that lasted into the 1930s, even though fresh ulcers at the site of the juncture were not uncommon.

The other end of the alimentary tract was also subjected to surgical intervention; cancers were removed from the large bowel and rectum with mortality rates that gradually fell from 80 to 60 to 20 to 12 percent as the surgeons developed their skill. In 1908 the British surgeon Ernest Miles carried out the first abdominoperineal resection for cancer of the rectum; that is, the cancer was attacked both from the abdomen and from below through the perineum (the area between the anus and the genitals), either by one surgeon, who actually did two operations, or by two working together. This technique formed the basis for all future developments.

Much of the new surgery in the abdomen was for cancer, but not all. Appendectomy became the accepted treatment for appendicitis (in appropriate cases) in the United States before the close of the 19th century; but in Great Britain surgeons were reluctant to remove the organ until 1902, when King Edward VII's coronation was dramatically postponed on account of his appendicitis. The publicity attached to his operation caused the disease and its surgical treatment to become fashionable—despite the fact that the royal appendix remained in the King's abdomen; the surgeon, Frederic Treves, had merely drained the abscess.

Appendectomy

Neurosurgery. Though probably the most demanding of all the surgical specialties, neurosurgery was nevertheless one of the first to emerge. The techniques and principles of general surgery were inadequate for work in such a delicate field. William Macewen, a Scottish general surgeon of outstanding versatility, and Victor Alexander Haden Horsley, the first British neurosurgeon, showed that the surgeon had much to offer in the treatment of disease of the brain and spinal cord. Macewen, in 1893, recorded 19 patients operated on for brain abscess, 18 of whom were cured; at that time most other surgeons had 100 percent mortality rates for the condition. His achievement remained unequaled until the discovery of penicillin.

An American, Harvey Williams Cushing, almost by himself consolidated neurosurgery as a specialty. From 1905 on, he advanced neurosurgery through a series of operations and through his writings. Tumours, epilepsy, trigeminal neuralgia, and pituitary disorders were among the conditions he treated successfully.

Radiology. In 1895 a development at the University of Würzburg had far-reaching effects on medicine and surgery, opening up an entirely fresh field of the diagnosis and study of disease and leading to a new form of

treatment, radiation therapy. This was the discovery of X rays by Wilhelm Conrad Röntgen, a professor of physics. Within months of the discovery there was an extensive literature on the subject: Robert Jones, a British surgeon, had localized a bullet in a boy's wrist before operating; stones in the urinary bladder and gallbladder had been demonstrated; and fractures had been displayed.

X rays in research

Experiments began on introducing substances that are opaque to X rays into the body to reveal organs and formations, both normal and abnormal. Walter Cannon, a Boston physiologist, used X rays in 1898 in his studies of the alimentary tract. Friedrich Voelcker, of Heidelberg, devised retrograde pyelography (introduction of the radiopaque medium into the kidney pelvis by way of the ureter) for the study of the urinary tract in 1905; in Paris in 1921, Jean Sicard X-rayed the spinal canal with the help of an oily iodine substance, and the next year he did the same for the bronchial tree; and in 1924 Evarts Graham, of St. Louis, used a radiopaque contrast medium to view the gallbladder. Air was also used to provide contrast; in 1918, at Johns Hopkins, Walter Dandy injected air into the ventricles (liquid-filled cavities) of the brain.

The problems of injecting contrast media into the blood vessels took longer to solve, and it was not until 1927 that António Moniz, of Lisbon, succeeded in obtaining pictures of the arteries of the brain. Eleven years later, George Robb and Israel Steinberg of New York overcame some of the difficulties of cardiac catheterization (introduction of a small tube into the heart by way of veins or arteries) and were able to visualize the chambers of the heart on X-ray film. After much research, a further refinement came in 1962, when Frank Sones and Earl K. Shirey of Cleveland showed how to introduce the contrast medium into the coronary arteries.

WORLD WAR I

The battlefields of the 20th century stimulated the progress of surgery and taught the surgeon innumerable lessons, which were subsequently applied in civilian practice. Regrettably, though, the principles of military surgery and casualty evacuation, which can be traced back to the Napoleonic wars, had to be learned over again.

World War I broke, quite dramatically, the existing surgical hierarchy and rule of tradition. No longer did the European surgeon have to waste his best years in apprenticeship before seating himself in his master's chair. Suddenly, young surgeons in the armed forces began confronting problems that would have daunted their elders. Furthermore, their training had been in "clean" surgery performed under aseptic conditions. Now they found themselves faced with the need to treat large numbers of grossly contaminated wounds in improvised theatres. They rediscovered debridement (the surgical excision of dead and dying tissue and the removal of foreign matter).

Treatment of contaminated wounds

The older surgeons cried "back to Lister," but antiseptics, no matter how strong, were no match for putrefaction and gangrene. One method of antiseptic irrigation—devised by Alexis Carrel and Henry Dakin and called the Carrel–Dakin treatment—was, however, beneficial, but only after the wound had been adequately debrided. The scourges of tetanus and gas gangrene were controlled to a large extent by antitoxin and antiserum injections, yet surgical treatment of the wound remained an essential requirement.

Abdominal casualties fared badly for the first year of the war, because experience in the utterly different circumstances of the South African War had led to a belief that these men were better left alone surgically. Fortunately, the error of continuing with such a policy 15 years later was soon appreciated, and every effort was made to deliver the wounded men to a suitable surgical unit with all speed. Little progress was made with chest wounds beyond opening up the wound even further to drain pus from the pleural cavity between the chest wall and the lungs.

Perhaps the most worthwhile and enduring benefit to flow from World War I was rehabilitation. For almost the first time, surgeons realized that their work did not end with a healed wound. In 1915 Robert Jones set up special facilities for orthopedic patients, and at about the same time Harold Gillies founded British plastic surgery in a hut at Sidcup, Kent. In 1917 Gillies popularized the pedicle type of skin graft (the type of graft in which skin and subcutaneous tissue are left temporarily attached for nourishment to the site from which the graft was taken). Since then plastic surgery has given many techniques and principles to other branches of surgery.

BETWEEN THE WORLD WARS

The years between the two world wars may conveniently be regarded as the time when surgery consolidated its position. A surprising number of surgical firsts and an amazing amount of fundamental research had been achieved even in the late 19th century, but the knowledge and experience could not be converted to practical use because the human body could not survive the onslaught. In the years between World Wars I and II, it was realized that physiology—in its widest sense, including biochemistry and fluid and electrolyte balance—was of major importance along with anatomy, pathology, and surgical technique.

The problem of shock. The first problem to be tackled was shock, which was, in brief, found to be due to a decrease in the effective volume of the circulation. To combat shock, the volume had to be restored, and the obvious substance was blood itself. In 1901 Karl Landsteiner, then in Austria, discovered the ABO blood groups, and in 1914 sodium citrate was added to freshly drawn blood to prevent clotting. Blood was occasionally transfused during World War I, but three-quarters of a pint was considered a large amount. These transfusions were given by directly linking the vein of a donor with that of the recipient. The continuous drip method, in which blood flows from a flask, was introduced by Hugh Marriott and Alan Kekwick at the Middlesex Hospital, London, in 1935.

Blood transfusion

As blood transfusions increased in frequency and volume, blood banks were required. Although it took another world war before these were organized on a large scale, the first tentative steps were taken by Sergey Sergeyevich Yudin, of Moscow, who, in 1933, used cadaver blood, and by Bernard Fantus, of Chicago, who, four years later, used living donors as his source of supply. Saline solution, plasma, artificial plasma expanders, and other solutions are now also used in the appropriate circumstances.

Sometimes after operations (especially abdominal operations), the gut becomes paralyzed. It is distended, and quantities of fluid pour into it, dehydrating the body. In 1932 Owen Wangensteen, at the University of Minnesota, advised decompressing the bowel, and in 1934 two other Americans, Thomas Miller and William Abbott, of Philadelphia, invented an apparatus for this purpose, a tube with an inflatable balloon on the end that could be passed into the small intestine. The fluid lost from the tissues was replaced by a continuous intravenous drip of saline solution on the principle described by Rudolph Matas, of New Orleans, in 1924. These techniques dramatically improved abdominal surgery, especially in cases of obstruction, peritonitis (inflammation of the abdominal membranes), and acute emergencies generally, since they made it possible to keep the bowel empty and at rest.

Anesthesia and thoracic surgery. The strides taken in anesthesia from the 1920s onward allowed surgeons much more freedom. Rectal anesthesia had never proved satisfactory, and the first improvement on the combination of nitrous oxide, oxygen, and ether was the introduction of the general anesthetic cyclopropane by Ralph Waters of Madison, Wis., in 1933. Soon afterward, intravenous anesthesia was introduced; John Lundy of the Mayo Clinic brought to a climax a long series of trials by many workers when he used Pentothal (thiopental sodium, a barbiturate) to put a patient peacefully to sleep. Then, in 1942, Harold Griffith and G. Enid Johnson, of Montreal, produced muscular paralysis by the injection of a purified preparation of curare. This was harmless since, by then, the anesthetist was able to control the patient's respiration.

If there was one person who was aided more than any other by the progress in anesthesia, it was the thoracic (chest) surgeon. What had bothered him previously was the collapse of the lung, which occurred whenever the pleural cavity was opened. Since the end of the 19th century, many and ingenious methods had been devised

Preventing lung collapse

to prevent this from happening. The best known was the negative pressure cabinet of Ernst Ferdinand Sauerbruch, then at Mikulicz' clinic at Breslau; the cabinet was first demonstrated in 1904 but was destined soon to become obsolete.

The solution lay in inhalational anesthesia administered under pressure. Indeed, when Théodore Tuffier, in 1891, successfully removed the apex of a lung for tuberculosis, this was the technique that he used; he even added an inflatable cuff around the tube inserted in the trachea to ensure a gas-tight fit. Tuffier was ahead of his time, however, and other surgeons and research workers wandered into confused and complex byways before Ivan Magill and Edgar Rowbotham, working at Gillies' plastic-surgery unit, found their way back to the simplicity of the endotracheal tube and positive pressure. In 1931 Ralph Waters showed that respiration could be controlled either by squeezing the anesthetic bag by hand or by using a small motor.

These advances allowed thoracic surgery to move into modern times. In the 1920s, operations had been performed mostly for infective conditions and as a last resort. The operations necessarily were unambitious and confined to collapse therapy, including thoracoplasty (removal of ribs), apicolysis (collapse of a lung apex and artificially filling the space), and phrenic crush (which paralyzed the diaphragm on the chosen side); to isolation of the area of lung to be removed by first creating pleural adhesions; and to drainage.

The technical problems of surgery within the chest were daunting until Harold Brunn of San Francisco reported six lobectomies (removals of lung lobes) for bronchiectasis with only one death. (In bronchiectasis one or more bronchi or bronchioles are chronically dilated and inflamed, with copious discharge of mucus mixed with pus.) The secret of Brunn's success was the use of intermittent suction after surgery to keep the cavity free of secretions until the remaining lobes of the lung could expand to fill the space. In 1931 Rudolf Nissen, in Berlin, removed an entire lung from a girl with bronchiectasis. She recovered to prove that the risks were not as bad as had been feared.

Cancer of the lung has become a major disease of the 20th century; perhaps it has genuinely increased, or perhaps modern techniques of diagnosis reveal it more often. As far back as 1913 a Welshman, Hugh Davies, removed a lower lobe for cancer, but a new era began when Evarts Graham removed a whole lung for cancer in 1933. The patient, a doctor, was still alive at the time of Graham's death in 1957.

The thoracic part of the esophagus is particularly difficult to reach, but in 1909 the British surgeon Arthur Evans successfully operated on it for cancer. But results were generally poor until, in 1944, John Garlock, of New York, showed that it is possible to excise the esophagus and to bring the stomach up through the chest and join it to the pharynx. Lengths of colon are also used as grafts to bridge the gap.

WORLD WAR II AND AFTER

Once the principles of military surgery were relearned and applied to modern warfare, instances of death, deformity, and loss of limb were reduced to levels previously unattainable. This was due largely to a thorough reorganization of the surgical services, adapting them to prevailing conditions, so that casualties received the appropriate treatment at the earliest possible moment. Evacuation by air (first used in World War I) helped greatly in this respect. Diagnostic facilities were improved, and progress in anesthesia kept pace with the surgeon's demands. Blood was transfused in adequate—and hitherto unthinkable—quantities, and the blood transfusion service as it is known today came into being.

Surgical specialization and teamwork reached new heights with the creation of units to deal with the special problems of injuries to different parts of the body. But the most revolutionary change was in the approach to wound infections brought about by the use of sulfonamides and (after 1941) of penicillin. The fact that these drugs could never replace meticulous wound surgery was, however, another lesson learned only in the bitter school of experience.

When the war ended, surgeons returned to civilian life feeling that they were at the start of a completely new, exciting era; and indeed they were, for the intense stimulation of the war years had led to developments in many branches of science that could now be applied to surgery. Nevertheless, it must be remembered that these developments merely allowed surgeons to realize the dreams of their fathers and grandfathers; they opened up remarkably few original avenues. The two outstanding phenomena of the 1950s and 1960s—heart surgery and organ transplantation—both originated in a real and practical manner at the turn of the century.

Support from other technologies. At first, perhaps, the surgeon tried to do too much himself, but before long his failures taught him to share his problems with experts in other fields. This was especially so with respect to difficulties of biomedical engineering and the exploitation of new materials. The relative protection from infection given by antibiotics and chemotherapy allowed the surgeon to become far more adventurous than hitherto in repairing and replacing damaged or worn-out tissues with foreign materials. Much research was still needed to find the best material for a particular purpose and to make sure that it would be acceptable to the body.

Use of plastics in surgery

Plastics, in their seemingly infinite variety, have come to be used for almost everything from suture material to heart valves; for strengthening the repair of hernias; for replacement of the head of the femur (first done by the French surgeon Jean Judet and his brother Robert-Louis Judet in 1950); for replacement of the lens of the eye after extraction of the natural lens for cataract; for valves to drain fluid from the brain in patients with hydrocephalus; and for many other applications. This is a far cry, indeed, from the unsatisfactory use of celluloid to restore bony defects of the face by the German surgeon Fritz Berndt in the 1890s. Inert metals, such as vitallium, have also found a place in surgery, largely in orthopedics for the repair of fractures and the replacement of joints.

The scope of surgery was further expanded by the introduction of the operating microscope. This brought the benefit of magnification particularly to neurosurgery and to ear surgery. In the latter it opened up a whole field of operations on the eardrum and within the middle ear. The principles of these operations were stated in 1951 and 1952 by two German surgeons, Fritz Zöllner and Horst Wullstein; and in 1952 Samuel Rosen of New York mobilized the footplate of the stapes to restore hearing in otosclerosis—a procedure attempted by the German Jean Kessel in 1876.

Although surgeons aim to preserve as much of the body as disease permits, they are sometimes forced to take radical measures to save life; when, for instance, cancer affects the pelvic organs. Pelvic exenteration (surgical removal of the pelvic organs and nearby structures) in two stages was devised by Allen Whipple of New York City, in 1935, and in one stage by Alexander Brunschwig, of Chicago, in 1937. Then, in 1960, Charles S. Kennedy, of Detroit, after a long discussion with Brunschwig, put into practice an operation that he had been considering for 12 years: hemicorporectomy—surgical removal of the lower part of the body. The patient died on the 11th day. The first successful hemicorporectomy (at the level between the lowest lumbar vertebra and the sacrum) was performed 18 months later by J. Bradley Aust and Karel B. Absolon, of Minnesota. This operation would never have been possible without all the technical, supportive, and rehabilitative resources of modern medicine.

Heart surgery. The attitude of the medical profession toward heart surgery was for long overshadowed by doubt and disbelief. Wounds of the heart could be sutured (first done successfully by Ludwig Rehn, of Frankfurt am Main, in 1896); the pericardial cavity—the cavity formed by the sac enclosing the heart—could be drained in purulent infections (as had been done by Larrey in 1824); and the pericardium could be partially excised for constrictive pericarditis when it was inflamed and constricted the movement of the heart (this operation was performed by Rehn and Sauerbruch in 1913). But little beyond these procedures found acceptance.

Heart operations of the early 20th century

Yet, in the first two decades of the 20th century, much experimental work had been carried out, notably by the French surgeons Théodore Tuffier and Alexis Carrel. Tuffier, in 1912, operated successfully on the aortic valve. In 1923 Elliott Cutler of Boston used a tenotome, a tendon-cutting instrument, to relieve a girl's mitral stenosis (a narrowing of the mitral valve between the upper and lower chambers of the left side of the heart) and in 1925, in London, Henry Souttar used a finger to dilate a mitral valve in a manner that was 25 years ahead of its time. Despite these achievements, there was too much experimental failure, and heart disease remained a medical, rather than surgical, matter.

Resistance began to crumble in 1938, when Robert Gross successfully tied off a persistent ductus arteriosus (a fetal blood vessel between the pulmonary artery and the aorta). It was finally swept aside in World War II by the remarkable record of Dwight Harken, who removed 134 missiles from the chest—13 in the heart chambers—without the loss of one patient.

After the war, advances came rapidly, with the initial emphasis on the correction or amelioration of congenital defects. Gordon Murray, of Toronto, made full use of his amazing technical ingenuity to devise and perform many pioneering operations. And Charles Bailey of Philadelphia, adopting a more orthodox approach, was responsible for establishing numerous basic principles in the growing specialty.

Until 1953, however, the techniques all had one great disadvantage: they were done "blind." The surgeon's dream was to stop the heart so that he could see what he was doing and be allowed more time in which to do it. In 1952 this dream began to come true when Floyd Lewis, of Minnesota, reduced the temperature of the body so as to lessen its need for oxygen while he closed a hole between the two upper heart chambers, the atria. The next year John Gibbon, Jr., of Philadelphia brought to fulfillment the research he had begun in 1937; he used his heart–lung machine to supply oxygen while he closed a hole in the septum between the atria.

Unfortunately, neither method alone was ideal, but intensive research and development led, in the early 1960s, to their being combined as extracorporeal cooling. That is, the blood circulated through a machine outside the body, which cooled it (and, after the operation, warmed it); the cooled blood lowered the temperature of the whole body. With the heart dry and motionless, the surgeon operated on the coronary arteries; he inserted plastic patches over holes; he sometimes almost remodeled the inside of the heart. But when it came to replacing valves destroyed by disease, he was faced with a difficult choice between human tissue and man-made valves, or even valves from animal sources.

Organ transplantation. In 1967 surgery arrived at a climax that made the whole world aware of its medico-surgical responsibilities when the South African surgeon Christiaan Barnard transplanted the first human heart. Reaction, both medical and lay, contained more than an element of hysteria. Yet, in 1964, James Hardy, of the University of Mississippi, had transplanted a chimpanzee's heart into a man; and in that year two prominent research workers, Richard Lower and Norman E. Shumway, had written: "Perhaps the cardiac surgeon should pause while society becomes accustomed to resurrection of the mythological chimera." Research had been remorselessly leading up to just such an operation ever since Charles Guthrie and Alexis Carrel, at the University of Chicago, perfected the suturing of blood vessels in 1905 and then carried out experiments in the transplantation of many organs, including the heart.

New developments in immunosuppression (the use of drugs to prevent organ rejection) have advanced the field of transplantation enormously. Kidney transplantation is now a routine procedure that is supplemented by dialysis with an artificial kidney (invented by Willem Kolff in wartime Holland) before and after the operation; mortality has been reduced to about 10 percent per year. Rejection of the transplanted heart by the patient's immune system was overcome to some degree in the 1980s with the introduction of the immunosuppressant cyclosporine; records show that many patients have lived for five or more years after the transplant operation.

The complexity of the liver and the unavailability of supplemental therapies such as the artificial kidney have contributed to the slow progress in liver transplantation (first performed in 1963 by Thomas Starzl). An increasing number of patients, especially children, have undergone successful transplantation; however, a substantial number may require retransplantation due to the failure of the first graft.

Lung transplants (first performed by Hardy in 1963) are difficult procedures, and much progress is yet to be made in preventing rejection. A combined heart-lung transplant is still in the experimental stage, but it is being met with increasing success; two-thirds of those receiving transplants are surviving, although complications such as infection are still common. Transplantation of all or part of the pancreas is not completely successful, and further refinements of the procedures (first performed in 1966 by Richard Lillehei) are needed. (R.G.R./Ed.)

THE PRACTICE OF MODERN MEDICINE

Health care and its delivery

The Alma-Ata declaration

The World Health Organization at its 1978 international conference held in the Soviet Union produced the Alma-Ata Health Declaration, which was designed to serve governments as a basis for planning health care that would reach people at all levels of society. The declaration reaffirmed that "health, which is a state of complete physical, mental and social well-being, and not merely the absence of disease or infirmity, is a fundamental human right and that the attainment of the highest possible level of health is a most important world-wide social goal whose realization requires the action of many other social and economic sectors in addition to the health sector." In its widest form the practice of medicine, that is to say the promotion and care of health, is concerned with this ideal.

ORGANIZATION OF HEALTH SERVICES

It is generally the goal of most countries to have their health services organized in such a way to ensure that individuals, families, and communities obtain the maximum benefit from current knowledge and technology available for the promotion, maintenance, and restoration of health. In order to play their part in this process, governments and other agencies are faced with numerous tasks, including the following: (1) They must obtain as much information as is possible on the size, extent, and urgency of their needs; without accurate information, planning can be misdirected. (2) These needs must then be revised against the resources likely to be available in terms of money, manpower, and materials; developing countries may well require external aid to supplement their own resources. (3) Based on their assessments, countries then need to determine realistic objectives and draw up plans. (4) Finally, a process of evaluation needs to be built into the program; the lack of reliable information and accurate assessment can lead to confusion, waste, and inefficiency.

Health services of any nature reflect a number of interrelated characteristics, among which the most obvious, but not necessarily the most important from a national point of view, is the curative function; that is to say, caring for those already ill. Others include special services that deal with particular groups (such as children or pregnant women) and with specific needs such as nutrition or immunization; preventive services, the protection of the health both of individuals and of communities; health education; and, as mentioned above, the collection and analysis of information.

Levels of health care. In the curative domain there are various forms of medical practice. They may be thought of generally as forming a pyramidal structure, with three tiers representing increasing degrees of specialization and technical sophistication but catering to diminishing numbers of patients as they are filtered out of the system at a lower level. Only those patients who require special attention either for diagnosis or treatment should reach the second (advisory) or third (specialized treatment) tiers where the cost per item of service becomes increasingly higher. The first level represents primary health care, or first contact care, at which patients have their initial contact with the health-care system.

Primary health care is an integral part of a country's health maintenance system, of which it forms the largest and most important part. As described in the declaration of Alma-Ata, primary health care should be "based on practical, scientifically sound and socially acceptable methods and technology made universally accessible to individuals and families in the community through their full participation and at a cost that the community and country can afford to maintain at every stage of their development." Primary health care in the developed countries is usually the province of a medically qualified physician: in the developing countries first contact care is often provided by nonmedically qualified personnel.

The vast majority of patients can be fully dealt with at the primary level. Those who cannot are referred to the second tier (secondary health care, or the referral services) for the opinion of a consultant with specialized knowledge or for X-ray examinations and special tests. Secondary health care often requires the technology offered by a local or regional hospital. Increasingly, however, the radiological and laboratory services provided by hospitals are available directly to the family doctor, thus improving his service to patients and increasing its range. The third tier of health care, employing specialist services, is offered by institutions such as teaching hospitals and units devoted to the care of particular groups—women, children, patients with mental disorders, and so on. The dramatic differences in the cost of treatment at the various levels is a matter of particular importance in developing countries, where the cost of treatment for patients at the primary health-care level is usually only a small fraction of that at the third level; medical costs at any level in such countries, however, are usually borne by the government.

Ideally, provision of health care at all levels will be available to all patients; such health care may be said to be universal. The well-off, both in relatively wealthy industrialized countries and in the poorer developing world, may be able to get medical attention from sources they prefer and can pay for in the private sector. The vast majority of people in most countries, however, are dependent in various ways upon health services provided by the state, to which they may contribute comparatively little or, in the case of poor countries, nothing at all.

Cost efficiency of health-care delivery

Costs of health care. The costs to national economics of providing health care are considerable and have been growing at a rapidly increasing rate, especially in countries such as the United States, Germany, and Sweden; the rise in Britain has been less rapid. This trend has been the cause of major concerns in both developed and developing countries. Some of this concern is based upon the lack of any consistent evidence to show that more spending on health care produces better health. There is a movement in developing countries to replace the type of organization of health-care services that evolved during European colonial times with some less expensive, and for them, more appropriate, health-care system.

In the industrialized world the growing cost of health services has caused both private and public health-care delivery systems to question current policies and to seek more economical methods of achieving their goals. Despite expenditures, health services are not always used effectively by those who need them, and results can vary widely from community to community. In Britain, for example, between 1951 and 1971 the death rate fell by 24 percent in the wealthier sections of the population but by only half that in the most underprivileged sections of society. The achievement of good health is reliant upon more than just the quality of health care. Health entails such factors as good education, safe working conditions, a favourable environment, amenities in the home, well-integrated social services, and reasonable standards of living.

In the developing countries. The developing countries differ from one another culturally, socially, and economically, but what they have in common is a low average income per person, with large percentages of their populations living at or below the poverty level. Although most have a small elite class, living mainly in the cities, the largest part of their populations live in rural areas. Urban regions in developing and some developed countries in the mid- and late 20th century have developed pockets of slums, which are growing because of an influx of rural peoples. For lack of even the simplest measures, vast numbers of urban and rural poor die each year of preventable and curable diseases, often associated with poor hygiene and sanitation, impure water supplies, malnutrition, vitamin deficiencies, and chronic preventable infections. The effect of these and other deprivations is reflected by the finding that in the 1980s the life expectancy at birth for men and women was about one-third less in Africa than it was in Europe; similarly, infant mortality in Africa was about eight times greater than in Europe. The extension of primary health-care services is therefore a high priority in the developing countries.

The developing countries themselves, lacking the proper resources, have often been unable to generate or implement the plans necessary to provide required services at the village or urban poor level. It has, however, become clear that the system of health care that is appropriate for one country is often unsuitable for another. Research has established that effective health care is related to the special circumstances of the individual country, its people, culture, ideology, and economic and natural resources.

Relating health-care systems to different cultures

The rising costs of providing health care have influenced a trend, especially among the developing nations, to promote services that employ less highly trained primary health-care personnel who can be distributed more widely in order to reach the largest possible proportion of the community. The principal medical problems to be dealt with in the developing world include undernutrition, infection, gastrointestinal disorders, and respiratory complaints, which themselves may be the result of poverty, ignorance, and poor hygiene. For the most part, these are easy to identify and to treat. Furthermore, preventive measures are usually simple and cheap. Neither treatment nor prevention requires extensive professional training: in most cases they can be dealt with adequately by the "primary health worker," a term that includes all nonprofessional health personnel.

In the developed countries. Those concerned with providing health care in the developed countries face a different set of problems. The diseases so prevalent in the Third World have, for the most part, been eliminated or are readily treatable. Many of the adverse environmental conditions and public health hazards have been conquered. Social services of varying degrees of adequacy have been provided. Public funds can be called upon to support the cost of medical care, and there are a variety of private insurance plans available to the consumer. Nevertheless, the funds that a government can devote to health care are limited and the cost of modern medicine continues to increase, thus putting adequate medical services beyond the reach of many. Adding to the expense of modern medical practices is the increasing demand for greater funding of health education and preventive measures specifically directed toward the poor. (Ha.Sc.)

ADMINISTRATION OF PRIMARY HEALTH CARE

In many parts of the world, particularly in developing countries, people get their primary health care, or first-contact care, where available at all, from nonmedically qualified personnel; these cadres of medical auxiliaries are being trained in increasing numbers to meet overwhelming needs among rapidly growing populations. Even among the comparatively wealthy countries of the world, containing in all a much smaller percentage of the world's

Medical auxiliary training

population, escalation in the costs of health services and in the cost of training a physician has precipitated some movement toward reappraisal of the role of the medical doctor in the delivery of first-contact care.

In advanced industrial countries, however, it is usually a trained physician who is called upon to provide the first-contact care. The patient seeking first-contact care can go either to a general practitioner or turn directly to a specialist. Which is the wisest choice has become a subject of some controversy. The general practitioner, however, is becoming rather rare in some developed countries. In countries where he does still exist, he is being increasingly observed as an obsolescent figure, because medicine covers an immense, rapidly changing, and complex field of which no physician can possibly master more than a small fraction. The very concept of the general practitioner, it is thus argued, may be absurd.

The obvious alternative to general practice is the direct access of a patient to a specialist. If a patient has problems with vision, he goes to an eye specialist, and if he has a pain in his chest (which he fears is due to his heart), he goes to a heart specialist. One objection to this plan is that the patient often cannot know which organ is responsible for his symptoms, and the most careful physician, after doing many investigations, may remain uncertain as to the cause. Breathlessness—a common symptom—may be due to heart disease, to lung disease, to anemia, or to emotional upset. Another common symptom is general malaise—feeling run-down or always tired; others are headache, chronic low backache, rheumatism, abdominal discomfort, poor appetite, and constipation. Some patients may also be overtly anxious or depressed. Among the most subtle medical skills is the ability to assess people with such symptoms and to distinguish between symptoms that are caused predominantly by emotional upset and those that are predominantly of bodily origin. A specialist may be capable of such a general assessment, but, often, with emphasis on his own subject, he fails at this point. The generalist with his broader training is often the better choice for a first diagnosis, with referral to a specialist as the next option.

It is often felt that there are also practical advantages for the patient in having his own doctor, who knows about his background, who has seen him through various illnesses, and who has often looked after his family as well. This personal physician, often a generalist, is in the best position to decide when the patient should be referred to a consultant.

The advantages of general practice and specialization are combined when the physician of first contact is a pediatrician. Although he sees only children and thus acquires a special knowledge of childhood maladies, he remains a generalist who looks at the whole patient. Another combination of general practice and specialization is represented by group practice, the members of which partially or fully specialize. One or more may be general practitioners, and one may be a surgeon, a second an obstetrician, a third a pediatrician, and a fourth an internist. In isolated communities group practice may be a satisfactory compromise, but in urban regions, where nearly everyone can be sent quickly to a hospital, the specialist surgeon working in a fully equipped hospital can usually provide better treatment than a general practitioner surgeon in a small clinic hospital.

MEDICAL PRACTICE IN DEVELOPED COUNTRIES

Britain. Before 1948, general practitioners in Britain settled where they could make a living. Patients fell into two main groups: weekly wage earners, who were compulsorily insured, were on a doctor's "panel" and were given free medical attention (for which the doctor was paid quarterly by the government); most of the remainder paid the doctor a fee for service at the time of the illness.

National Health Service

In 1948 the National Health Service began operation. Under its provisions, everyone is entitled to free medical attention with a general practitioner with whom he is registered. Though general practitioners in the National Health Service are not debarred from also having private patients, these must be people who are not registered with them under the National Health Service. Any physician is free to work as a general practitioner entirely independent of the National Health Service, though there are few who do so. Almost the entire population is registered with a National Health Service general practitioner, and the vast majority automatically sees this physician, or one of his partners, when they require medical attention. A few people, mostly wealthy, while registered with a National Health Service general practitioner, regularly see another physician privately; and a few may occasionally seek a private consultation because they are dissatisfied with their National Health Service physician.

A general practitioner under the National Health Service remains an independent contractor, paid by a capitation fee; that is, according to the number of people registered with him. He may work entirely from his own office, and he provides and pays his own receptionist, secretary, and other ancillary staff. Most general practitioners have one or more partners and work more and more in premises built for the purpose. Some of these structures are erected by the physicians themselves, but many are provided by the local authority, the physicians paying rent for using them. Health centres, in which groups of general practitioners work have become common.

In Britain only a small minority of general practitioners can admit patients to a hospital and look after them personally. Most of this minority are in country districts, where, before the days of the National Health Service, there were cottage hospitals run by general practitioners; many of these hospitals continued to function in a similar manner. All general practitioners use such hospital facilities as X-ray departments and laboratories, and many general practitioners work in hospitals in emergency rooms (casualty departments) or as clinical assistants to consultants, or specialists.

General practitioners are spread more evenly over the country than formerly, when there were many in the richer areas and few in the industrial towns. The maximum allowed list of National Health Service patients per doctor is 3,500; the average is about 2,500. Patients have free choice of the physician with whom they register, with the proviso that they cannot be accepted by one who already has a full list and that a physician can refuse to accept them (though such refusals are rare). In remote rural places there may be only one physician within a reasonable distance.

Home visitations

Until the mid-20th century it was not unusual for the doctor in Britain to visit patients in their own homes. A general practitioner might make 15 or 20 such house calls in a day, as well as seeing patients in his office or "surgery," often in the evenings. This enabled him to become a family doctor in fact as well as in name. In modern practice, however, a home visit is quite exceptional and is paid only to the severely disabled or seriously ill when other recourses are ruled out. All patients are normally required to go to the doctor.

It has also become unusual for a personal doctor to be available during weekends or holidays. His place may be taken by one of his partners in a group practice, a provision that is reasonably satisfactory. General practitioners, however, may now use one of several commercial deputizing services that employs young doctors to be on call. Although some of these young doctors may be well experienced, patients do not generally appreciate this kind of arrangement. (J.W.T./Ha.Sc.)

United States. Whereas in Britain the doctor of first contact is regularly a general practitioner, in the United States the nature of first-contact care is less consistent.

Decline of general practice

General practice in the United States has been in a state of decline in the second half of the 20th century, especially in metropolitan areas. The general practitioner, however, is being replaced to some degree by the growing field of family practice. In 1969 family practice was recognized as a medical specialty after the American Academy of General Practice (now the American Academy of Family Physicians) and the American Medical Association created the American Board of General (now Family) Practice. Since that time the field has become one of the larger medical specialties in the United States. The family physi-

cians were the first group of medical specialists in the United States for whom recertification was required.

There is no national health service, as such, in the United States. Most physicians in the country have traditionally been in some form of private practice, whether seeing patients in their own offices, clinics, medical centres, or another type of facility and regardless of the patients' income. Doctors are usually compensated by such state and federally supported agencies as Medicaid (for treating the poor) and Medicare (for treating the elderly); not all doctors, however, accept poor patients. There are also some state-supported clinics and hospitals where the poor and elderly may receive free or low-cost treatment, and some doctors devote a small percentage of their time to treatment of the indigent. Veterans may receive free treatment at Veterans Administration hospitals, and the federal government through its Indian Health Service provides medical services to American Indians and Alaskan natives, sometimes using trained auxiliaries for first-contact care.

In the rural United States first-contact care is likely to come from a generalist. The middle- and upper-income groups living in urban areas, however, have access to a larger number of primary medical care options. Children are often taken to pediatricians, who may oversee the child's health needs until adulthood. Adults frequently make their initial contact with an internist, whose field is mainly that of medical (as opposed to surgical) illnesses; the internist often becomes the family physician. Other adults choose to go directly to physicians with narrower specialties, including dermatologists, allergists, gynecologists, orthopedists, and ophthalmologists.

Patients in the United States may also choose to be treated by doctors of osteopathy. These doctors are fully qualified, but they make up only a small percentage of the country's physicians. They may also branch off into specialties, but general practice is much more common in their group than among M.D.'s.

It used to be more common in the United States for physicians providing primary care to work independently, providing their own equipment and paying their own ancillary staff. In smaller cities they mostly had full hospital privileges, but in larger cities these privileges were more likely to be restricted. Physicians, often sharing the same specialties, are increasingly entering into group associations, where the expenses of office space, staff, and equipment may be shared; such associations may work out of suites of offices, clinics, or medical centres. The increasing competition and risks of private practice have caused many physicians to join Health Maintenance Organizations (HMOs), which provide comprehensive medical care and hospital care on a prepaid basis. The cost savings to patients are considerable, but they must use only the HMO doctors and facilities. HMOs stress preventive medicine and out-patient treatment as opposed to hospitalization as a means of reducing costs, a policy that has caused an increased number of empty hospital beds in the United States.

Health Maintenance Organizations

While the number of doctors per 100,000 population in the United States has been steadily increasing, there has been a trend among physicians toward the use of trained medical personnel to handle some of the basic services normally performed by the doctor. So-called physician extender services are commonly divided into nurse practitioners and physician's assistants, both of whom provide similar ancillary services for the general practitioner or specialist. Such personnel do not replace the doctor. Almost all American physicians have systems for taking each other's calls when they become unavailable. House calls in the United States, as in Britain, have become exceedingly rare. (Ed.)

Russia. In Russia general practitioners are prevalent in the thinly populated rural areas. Pediatricians deal with children up to about age 15. Internists look after the medical ills of adults, and occupational physicians deal with the workers, sharing care with internists.

Teams of physicians with experience in varying specialties work from polyclinics or outpatient units, where many types of diseases are treated. Small towns usually have one polyclinic to serve all purposes. Large cities commonly have separate polyclinics for children and adults, as well as clinics with specializations such as women's health care, mental illnesses, and sexually transmitted diseases. Polyclinics usually have X-ray apparatus and facilities for examination of tissue specimens, facilities associated with the departments of the district hospital. Beginning in the late 1970s was a trend toward the development of more large, multipurpose treatment centres, first-aid hospitals, and specialized medicine and health care centres.

Polyclinics

Home visits have traditionally been common, and much of the physician's time is spent in performing routine checkups for preventive purposes. Some patients in sparsely populated rural areas may be seen first by feldshers (auxiliary health workers), nurses, or midwives who work under the supervision of a polyclinic or hospital physician. The feldsher was once a lower-grade physician in the army or peasant communities, but feldshers are now regarded as paramedical workers.

Japan. In Japan, with less rigid legal restriction of the sale of pharmaceuticals than in the West, there was formerly a strong tradition of self-medication and self-treatment. This was modified in 1961 by the institution of health insurance programs that covered a large proportion of the population; there was then a great increase in visits to the outpatient clinics of hospitals and to private clinics and individual physicians.

When Japan shifted from traditional Chinese medicine with the adoption of Western medical practices in the 1870s, Germany became the chief model. As a result of German influence and of their own traditions, Japanese physicians tended to prefer professorial status and scholarly research opportunities at the universities or positions in the national or prefectural hospitals to private practice. There were some pioneering physicians, however, who brought medical care to the ordinary people.

Physicians in Japan have tended to cluster in the urban areas. The Medical Service Law of 1963 was amended to empower the Ministry of Health and Welfare to control the planning and distribution of future public and nonprofit medical facilities, partly to redress the urban-rural imbalance. Meanwhile, mobile services were expanded.

The influx of patients into hospitals and private clinics after the passage of the national health insurance acts of 1961 had, as one effect, a severe reduction in the amount of time available for any one patient. Perhaps in reaction to this situation, there has been a modest resurgence in the popularity of traditional Chinese medicine, with its leisurely interview, its dependence on herbal and other "natural" medicines, and its other traditional diagnostic and therapeutic practices. The rapid aging of the Japanese population as a result of the sharply decreasing death rate and birth rate has created an urgent need for expanded health care services for the elderly. There has also been an increasing need for centres to treat health problems resulting from environmental causes.

Other developed countries. On the continent of Europe there are great differences both within single countries and between countries in the kinds of first-contact medical care. General practice, while declining in Europe as elsewhere, is still rather common even in some large cities, as well as in remote country areas.

Medical practice in Europe

In The Netherlands, departments of general practice are administered by general practitioners in all the medical schools—an exceptional state of affairs—and general practice flourishes. In the larger cities of Denmark, general practice on an individual basis is usual and popular, because the physician works only during office hours. In addition, there is a duty doctor service for nights and weekends. In the cities of Sweden, primary care is given by specialists. In the remote regions of northern Sweden, district doctors act as general practitioners to patients spread over huge areas; the district doctors delegate much of their home visiting to nurses.

In France there are still general practitioners, but their number is declining. Many medical practitioners advertise themselves directly to the public as specialists in internal medicine, ophthalmologists, gynecologists, and other kinds of specialists. Even when patients have a general practitioner, they may still go directly to a specialist. At-

tempts to stem the decline in general practice are being made by the development of group practice and of small rural hospitals equipped to deal with less serious illnesses, where general practitioners can look after their patients.

Although Israel has a high ratio of physicians to population, there is a shortage of general practitioners, and only in rural areas is general practice common. In the towns many people go directly to pediatricians, gynecologists, and other specialists, but there has been a reaction against this direct access to the specialist. More general practitioners have been trained, and the Israel Medical Association has recommended that no patient should be referred to a specialist except by the family physician or on instructions given by the family nurse. At Tel Aviv University there is a department of family medicine. In some newly developing areas, where the doctor shortage is greatest, there are medical centres at which all patients are initially interviewed by a nurse. The nurse may deal with many minor ailments, thus freeing the physician to treat the more seriously ill.

Nearly half the medical doctors in Australia are general practitioners—a far higher proportion than in most other advanced countries—though, as elsewhere, their numbers are declining. They tend to do far more for their patients than in Britain, many performing such operations as removal of the appendix, gallbladder, or uterus, operations that elsewhere would be carried out by a specialist surgeon. Group practices are common.

MEDICAL PRACTICE IN DEVELOPING COUNTRIES

China. Health services in China since the Cultural Revolution have been characterized by decentralization and dependence on personnel chosen locally and trained for short periods. Emphasis is given to selfless motivation, self-reliance, and to the involvement of everyone in the community. Campaigns stressing the importance of preventive measures and their implementation have served to create new social attitudes as well as to break down divisions between different categories of health workers. Health care is regarded as a local matter that should not require the intervention of any higher authority; it is based upon a highly organized and well-disciplined system that is egalitarian rather than hierarchical, as in Western societies, and which is well suited to the rural areas where about two-thirds of the population live. In the large and crowded cities an important constituent of the health-care system is the residents' committees, each for a population of 1,000 to 5,000 people. Care is provided by part-time personnel with periodic visits by a doctor. A number of residents' committees are grouped together into neighbourhoods of some 50,000 people where there are clinics and general hospitals staffed by doctors as well as health auxiliaries trained in both traditional and Westernized medicine. Specialized care is provided at the district level (over 100,000 people), in district hospitals and in epidemic and preventive medicine centres. In many rural districts people's communes have organized cooperative medical services that provide primary care for a small annual fee.

Residents' committees

Throughout China the value of traditional medicine is stressed, especially in the rural areas. All medical schools are encouraged to teach traditional medicine as part of their curriculum, and efforts are made to link colleges of Chinese medicine with Western-type medical schools. Medical education is of shorter duration than it is in Europe, and there is greater emphasis on practical work. Students spend part of their time away from the medical school working in factories or in communes; they are encouraged to question what they are taught and to participate in the educational process at all stages. One well-known form of traditional medicine is acupuncture, which is used as a therapeutic and pain-relieving technique; requiring the insertion of brass-handled needles at various points on the body, acupuncture has become quite prominent as a form of anesthesia.

Acupuncture

The vast number of nonmedically qualified health staff, upon whom the health-care system greatly depends, includes both full-time and part-time workers. The latter include so-called barefoot doctors, who work mainly in rural areas, worker doctors in factories, and medical workers in residential communities. None of these groups is medically qualified. They have had only a three-month period of formal training, part of which is done in a hospital, fairly evenly divided between theoretical and practical work. This is followed by a varying period of on-the-job experience under supervision.

India. Āyurvedic medicine is an example of a well-organized system of traditional health care, both preventive and curative, that is widely practiced in parts of Asia. Āyurvedic medicine has a long tradition behind it, having originated in India perhaps as long as 3,000 years ago. It is still a favoured form of health care in large parts of the Eastern world, especially in India, where a large percentage of the population use this system exclusively or combined with modern medicine. The Indian Medical Council was set up in 1971 by the Indian government to establish maintenance of standards for undergraduate and postgraduate education. It establishes suitable qualifications in Indian medicine and recognizes various forms of traditional practice including Āyurvedic, Unani, and Siddha. Projects have been undertaken to integrate the indigenous Indian and Western forms of medicine. Most Āyurvedic practitioners work in rural areas, providing health care to at least 500,000,000 people in India alone. They therefore represent a major force for primary health care, and their training and deployment are important to the government of India.

Āyurvedic medicine

Like scientific medicine, Āyurvedic medicine has both preventive and curative aspects. The preventive component emphasizes the need for a strict code of personal and social hygiene, the details of which depend upon individual, climatic, and environmental needs. Bodily exercises, the use of herbal preparations, and Yoga form a part of the remedial measures. The curative aspects of Āyurvedic medicine involves the use of herbal medicines, external preparations, physiotherapy, and diet. It is a principle of Āyurvedic medicine that the preventive and therapeutic measures be adapted to the personal requirements of each patient.

Other developing countries. A main goal of the World Health Organization (WHO), as expressed in the Alma-Ata Declaration of 1978, is to provide to all the citizens of the world a level of health that will allow them to lead socially and economically productive lives by the year 2000. By the late 1980s, however, vast disparities in health care still existed between the rich and poor countries of the world. In developing countries such as Ethiopia, Guinea, Mali, and Mozambique, for instance, governments in the late 1980s spent less than $5 per person per year on public health, while in most western European countries several hundred dollars per year was spent on each person. The disproportion of the number of physicians available between developing and developed countries is similarly wide.

Along with the shortage of physicians, there is a shortage of everything else needed to provide medical care—of equipment, drugs, and suitable buildings, and of nurses, technicians, and all other grades of staff, whose presence is taken for granted in the affluent societies. Yet there are greater percentages of sick in the poor countries than in the rich countries. In the poor countries a high proportion of people are young, and all are liable to many infections, including tuberculosis, syphilis, typhoid, and cholera (which, with the possible exception of syphilis, are now rare in the rich countries), and also malaria, yaws, worm infestations, and many other conditions occurring primarily in the warmer climates. Nearly all of these infections respond to the antibiotics and other drugs that have been discovered since the 1920s. There is also much malnutrition and anemia, which can be cured if funding is available. There is a prevalence of disorders remediable by surgery. Preventive medicine can ensure clean water supplies, destroy insects that carry infections, teach hygiene, and show how to make the best use of resources.

Medical needs in developing countries

In most poor countries there are a few people, usually living in the cities, who can afford to pay for medical care, and in a free market system the physicians tend to go where they can make the best living; this situation causes the doctor–patient ratio to be much higher in the towns

than in country districts. A physician in Bombay or in Rio de Janeiro, for example, may have equipment as lavish as that of a physician in the United States and can earn an excellent income. The poor, however, both in the cities and in the country, can get medical attention only if it is paid for by the state, by some supranational body, or by a mission or other charitable organization. Moreover, the quality of the care they receive is often poor, and in remote regions it may be lacking altogether. In practice, hospitals run by a mission may cooperate closely with state-run health centres.

Because physicians are scarce, their skills must be used to best advantage, and much of the work normally done by physicians in the rich countries has to be delegated to auxiliaries or nurses, who have to diagnose the common conditions, give treatment, take blood samples, help with operations, supply simple posters containing health advice, and carry out other tasks. In such places the doctor has time only to perform major operations and deal with the more difficult medical problems. People are treated as far as possible on an outpatient basis from health centres housed in simple buildings; few can travel except on foot, and, if they are more than a few miles from a health centre, they tend not to go there. Health centres also may be used for health education.

Health care in Tanzania

Although primary health-care service differs from country to country, that developed in Tanzania is representative of many that have been devised in largely rural developing countries. The most important feature of the Tanzanian rural health service is the rural health centre, which, with its related dispensaries, is intended to provide comprehensive health services for the community. The staff is headed by the assistant medical officer and the medical assistant. The assistant medical officer has at least four years of experience, which is then followed by further training for 18 months. He is not a doctor but serves to bridge the gap between medical assistant and physician. The medical assistant has three years of general medical education. The work of the rural health centres and dispensaries is mainly of three kinds: diagnosis and treatment, maternal and child health, and environmental health. The main categories of primary health workers also include medical aids, maternal and child health aids, and health auxiliaries. Nurses and midwives form another category of worker. In the villages there are village health posts staffed by village medical helpers working under supervision from the rural health centre.

Primitive medicine

In some primitive elements of the societies of developing countries, and of some developed countries, there exists the belief that illness comes from the displeasure of ancestral gods and evil spirits, from the malign influence of evilly disposed persons, or from natural phenomena that can neither be forecast nor controlled. To deal with such causes there are many varieties of indigenous healers who practice elaborate rituals on behalf of both the physically ill and the mentally afflicted. If it is understood that such beliefs, and other forms of shamanism, may provide a basis upon which health care can be based, then primary health care may be said to exist almost everywhere. It is not only easily available but also readily acceptable, and often preferred, to more rational methods of diagnosis and treatment. Although such methods may sometimes be harmful, they may often be effective, especially where the cause is psychosomatic. Other patients, however, may suffer from a disease for which there is a cure in modern medicine.

In order to improve the coverage of primary health-care services and to spread more widely some of the benefits of Western medicine, attempts have sometimes been made to find a means of cooperation, or even integration, between traditional and modern medicine (see above *India*). In Africa, for example, some such attempts are officially sponsored by ministries of health, state governments, universities, and the like, and they have the approval of WHO, which often takes the lead in this activity. In view, however, of the historical relationships between these two systems of medicine, their different basic concepts, and the fact that their methods cannot readily be combined, successful merging has been limited.

ALTERNATIVE OR COMPLEMENTARY MEDICINE

Persons dissatisfied with the methods of modern medicine or with its results sometimes seek help from those professing expertise in other, less conventional, and sometimes controversial, forms of health care. Such practitioners are not medically qualified unless they are combining such treatments with a regular (allopathic) practice, which includes osteopathy. In many countries the use of some forms, such as chiropractic, requires licensing and a degree from an approved college. The treatments afforded in these various practices are not always subjected to objective assessment, yet they provide services that are alternative, and sometimes complementary, to conventional practice. This group includes practitioners of homeopathy, naturopathy, acupuncture, hypnotism, and various meditative and quasi-religious forms. Numerous persons also seek out some form of faith healing to cure their ills, sometimes as a means of last resort. Religions commonly include some advents of miraculous curing within their scriptures. The belief in such curative powers has been in part responsible for the increasing popularity of the television, or "electronic," preacher in the United States, a phenomenon that involves millions of viewers. Millions of others annually visit religious shrines, such as the one at Lourdes in France, with the hope of being miraculously healed.

SPECIAL PRACTICES AND FIELDS OF MEDICINE

Specialties in medicine. At the beginning of World War II it was possible to recognize a number of major medical specialties, including internal medicine, obstetrics and gynecology, pediatrics, pathology, anesthesiology, ophthalmology, surgery, orthopedic surgery, plastic surgery, psychiatry and neurology, radiology, and urology. Hematology was also an important field of study, and microbiology and biochemistry were important medically allied specialties. Since World War II, however, there has been an almost explosive increase of knowledge in the medical sciences as well as enormous advances in technology as applicable to medicine. These developments have led to more and more specialization. The knowledge of pathology has been greatly extended, mainly by the use of the electron microscope; similarly microbiology, which includes bacteriology, expanded with the growth of such other subfields as virology (the study of viruses) and mycology (the study of yeasts and fungi in medicine). Biochemistry, sometimes called clinical chemistry or chemical pathology, has contributed to the knowledge of disease, especially in the field of genetics where genetic engineering has become a key to curing some of the most difficult diseases. Hematology also expanded after World War II with the development of electron microscopy. Contributions to medicine have come from such fields as psychology and sociology especially in such areas as mental disorders and mental handicaps. Clinical pharmacology has led to the development of more effective drugs and to the identification of adverse reactions. More recently established medical specialties are those of preventive medicine, physical medicine and rehabilitation, family practice, and nuclear medicine. In the United States every medical specialist must be certified by a board composed of members of the specialty in which certification is sought. Some type of peer certification is required in most countries.

Certification

Expansion of knowledge both in depth and in range has encouraged the development of new forms of treatment that require high degrees of specialization, such as organ transplantation and exchange transfusion; the field of anesthesiology has grown increasingly complex as equipment and anesthetics have improved. New technologies have introduced microsurgery, laser beam surgery, and lens implantation (for cataract patients), all requiring the specialist's skill. Precision in diagnosis has markedly improved; advances in radiology, the use of ultrasound, computerized axial tomography (CAT scan), and nuclear magnetic resonance imaging are examples of the extension of technology requiring expertise in the field of medicine.

To provide more efficient service it is not uncommon for a specialist surgeon and a specialist physician to form a team working together in the field of, for example, heart

disease. An advantage of this arrangement is that they can attract a highly trained group of nurses, technologists, operating room technicians, and so on, thus greatly improving the efficiency of the service to the patient. Such specialization is expensive, however, and has required an increasingly large proportion of the health budget of institutions, a situation that eventually has its financial effect on the individual citizen. The question therefore arises as to their cost-effectiveness. Governments of developing countries have usually found, for instance, that it is more cost-efficient to provide more people with basic care.

Teaching. Physicians in developed countries frequently prefer posts in hospitals with medical schools. Newly qualified physicians want to work there because doing so will aid their future careers, though the actual experience may be wider and better in a hospital without a medical school.

Advantage of medical school association

Senior physicians seek careers in hospitals with medical schools because consultant, specialist, or professorial posts there usually carry a high degree of prestige. When the posts are salaried, the salaries are sometimes, but not always, higher than in a nonteaching hospital. Usually a consultant who works in private practice earns more when on the staff of a medical school.

In many medical schools there are clinical professors in each of the major specialties—such as surgery, internal medicine, obstetrics and gynecology, and psychiatry—and often of the smaller specialties as well. There are also professors of pathology, radiology, and radiotherapy. Whether professors or not, all doctors in teaching hospitals have the two functions of caring for the sick and educating students. They give lectures and seminars and are accompanied by students on ward rounds.

Industrial medicine. The Industrial Revolution greatly changed, and as a rule worsened, the health hazards caused by industry, while the numbers at risk vastly increased. In Britain the first small beginnings of efforts to ameliorate the lot of the workers in factories and mines began in 1802 with the passing of the first factory act, the Health and Morals of Apprentices Act. The factory act of 1838, however, was the first truly effective measure in the industrial field. It forbade night work for children and restricted their work hours to 12 per day. Children under 13 were required to attend school. A factory inspectorate was established, the inspectors being given powers of entry into factories and power of prosecution of recalcitrant owners. Thereafter there was a succession of acts with detailed regulations for safety and health in all industries. Industrial diseases were made notifiable, and those who developed any prescribed industrial disease were entitled to benefits.

Industrial physician's function

The situation is similar in other developed countries. Physicians are bound by legal restrictions and must report industrial diseases. The industrial physician's most important function, however, is to prevent industrial diseases. Many of the measures to this end have become standard practice, but, especially in industries working with new substances, the physician should determine if workers are being damaged and suggest preventive measures. The industrial physician may advise management about industrial hygiene and the need for safety devices and protective clothing and may become involved in building design. The physician or health worker may also inform the worker of occupational health hazards.

Modern factories usually have arrangements for giving first aid in case of accidents. Depending upon the size of the plant, the facilities may range from a simple first-aid station to a large suite of lavishly equipped rooms and may include a staff of qualified nurses and physiotherapists and one or perhaps more full-time physicians.

Periodic medical examination. Physicians in industry carry out medical examinations, especially on new employees and on those returning to work after sickness or injury. In addition, those liable to health hazards may be examined regularly in the hope of detecting evidence of incipient damage. In some organizations every employee may be offered a regular medical examination.

The industrial and the personal physician. When a worker also has a personal physician, there may be doubt, in some cases, as to which physician bears the main responsibility for his health. When someone has an accident or becomes acutely ill at work, the first aid is given or directed by the industrial physician. Subsequent treatment may be given either at the clinic at work or by the personal physician. Because of labour-management difficulties, workers sometimes tend not to trust the diagnosis of the management-hired physician.

Industrial health services. During the epoch of the Soviet Union and the Soviet bloc, industrial health service generally developed more fully in those countries than in the capitalist countries. At the larger industrial establishments in the Soviet Union, polyclinics were created to provide both occupational and general care for workers and their families. Occupational physicians were responsible for preventing occupational diseases and injuries, health screening, immunization, and health education.

In the capitalist countries, on the other hand, no fixed pattern of industrial health service has emerged. Legislation impinges upon health in various ways, including the provision of safety measures, the restriction of pollution, and the enforcement of minimum standards of lighting, ventilation, and space per person. In most of these countries there is found an infinite variety of schemes financed and run by individual firms or, equally, by huge industries. Labour unions have also done much to enforce health codes within their respective industries. In the developing countries there has been generally little advance in industrial medicine.

Family health care. In many societies special facilities are provided for the health care of pregnant women, mothers, and their young children. The health care needs of these three groups are generally recognized to be so closely related as to require a highly integrated service that includes prenatal care, the birth of the baby, the postnatal period, and the needs of the infant. Such a continuum should be followed by a service attentive to the needs of young children and then by a school health service. Family clinics are common in countries that have state-sponsored health services, such as those in the United Kingdom and elsewhere in Europe. Family health care in some developed countries, such as the United States, is provided for low-income groups by state-subsidized facilities, but other groups defer to private physicians or privately run clinics.

The prenatal clinic

Prenatal clinics provide a number of elements. There is, first, the care of the pregnant woman, especially if she is in a vulnerable group likely to develop some complication during the last few weeks of pregnancy and subsequent delivery. Many potential hazards, such as diabetes and high blood pressure, can be identified and measures taken to minimize their effects. In developing countries pregnant women are especially susceptible to many kinds of disorders, particularly infections such as malaria. Local conditions determine what special precautions should be taken to ensure a healthy child. Most pregnant women, in their concern to have a healthy child, are receptive to simple health education. The prenatal clinic provides an excellent opportunity to teach the mother how to look after herself during pregnancy, what to expect at delivery, and how to care for her baby. If the clinic is attended regularly, the woman's record will be available to the staff that will later supervise the delivery of the baby; this is particularly important for someone who has been determined to be at risk. The same clinical unit should be responsible for prenatal, natal, and postnatal care as well as for the care of the newborn infants.

Most pregnant women can be safely delivered in simple circumstances without an elaborately trained staff or sophisticated technical facilities, provided that these can be called upon in emergencies. In developed countries it was customary in premodern times for the delivery to take place in the woman's home supervised by a qualified midwife or by the family doctor. By the mid-20th century women, especially in urban areas, usually preferred to have their babies in a hospital, either in a general hospital or in a more specialized maternity hospital. In many developing countries traditional birth attendants supervise the delivery. They are women, for the most part without formal training, who have acquired skill by working with others and from their own experience. Normally they belong to the local community where they have the confidence of

the family, where they are content to live and serve, and where their services are of great value. In many developing countries the better training of birth attendants has a high priority. In developed Western countries there has been a trend toward delivery by natural childbirth, including delivery in a hospital without anesthesia, and home delivery.

Postnatal health care

Postnatal care services are designed to supervise the return to normal of the mother. They are usually given by the staff of the same unit that was responsible for the delivery. Important considerations are the matter of breast- or artificial feeding and the care of the infant. Today the prospects for survival of babies born prematurely or after a difficult and complicated labour, as well as for neonates (recently born babies) with some physical abnormality, are vastly improved. This is due to technical advances, including those that can determine defects in the prenatal stage, as well as to the growth of neonatology as a specialty. A vital part of the family health-care service is the child welfare clinic, which undertakes the care of the newborn. The first step is the thorough physical examination of the child on one or more occasions to determine whether or not it is normal both physically and, if possible, mentally. Later periodic examinations serve to decide if the infant is growing satisfactorily. Arrangements can be made for the child to be protected from major hazards by, for example, immunization and dietary supplements. Any intercurrent condition, such as a chest infection or skin disorder, can be detected early and treated. Throughout the whole of this period mother and child are together, and particular attention is paid to the education of the mother for the care of the child.

A part of the health service available to children in the developed countries is that devoted to child guidance. This provides psychiatric guidance to maladjusted children usually through the cooperative work of a child psychiatrist, educational psychologist, and schoolteacher.

Geriatrics. Since the mid-20th century a change has occurred in the population structure in developed countries. The proportion of elderly people has been increasing.

Increasing need for elderly care

Since 1983, however, in most European countries the population growth of that group has leveled off, although it is expected to continue to grow more rapidly than the rest of the population in most countries through the first third of the 21st century. In the late 20th century Japan had the fastest growing elderly population.

Geriatrics, the health care of the elderly, is therefore a considerable burden on health services. In the United Kingdom about one-third of all hospital beds are occupied by patients over 65; half of these are psychiatric patients. The physician's time is being spent more and more with the elderly, and since statistics show that women live longer than men, geriatric practice is becoming increasingly concerned with the treatment of women. Elderly people often have more than one disorder, many of which are chronic and incurable, and they need more attention from health-care services. In the United States there has been some movement toward making geriatrics a medical specialty, but it has not generally been recognized.

Support services for the elderly provided by private or state-subsidized sources include domestic help, delivery of meals, day-care centres, elderly residential homes or nursing homes, and hospital beds either in general medical wards or in specialized geriatric units. The degree of accessibility of these services is uneven from country to country and within countries. In the United States, for instance, although there are some federal programs, each state has its own elderly programs, which vary widely. However, as the elderly become an increasingly larger part of the population their voting rights are providing increased leverage for obtaining more federal and state benefits. The general practitioner or family physician working with visiting health and social workers and in conjunction with the patient's family often form a working team for elderly care.

In the developing world, countries are largely spared such geriatric problems, but not necessarily for positive reasons. A principal cause, for instance, is that people do not live so long. Another major reason is that in the extended family concept, still prevalent among developing countries, most of the caretaking needs of the elderly are provided by the family.

Public health practice. The physician working in the field of public health is mainly concerned with the environmental causes of ill health and in their prevention. Bad drainage, polluted water and atmosphere, noise and smells, infected food, bad housing, and poverty in general are all his special concern. Perhaps the most descriptive title he can be given is that of community physician. In Britain he has been customarily known as the medical officer of health and, in the United States, as the health officer.

Public health measures of the 19th century

The spectacular improvement in the expectation of life in the affluent countries has been due far more to public health measures than to curative medicine. These public health measures began operation largely in the 19th century. At the beginning of that century, drainage and water supply systems were all more or less primitive; nearly all the cities of that time had poorer water and drainage systems than Rome had possessed 1,800 years previously. Infected water supplies caused outbreaks of typhoid, cholera, and other waterborne infections. By the end of the century, at least in the larger cities, water supplies were usually safe. Food-borne infections were also drastically reduced by the enforcement of laws concerned with the preparation, storage, and distribution of food. Insect-borne infections, such as malaria and yellow fever, which were common in tropical and semitropical climates, were eliminated by the destruction of the responsible insects. Fundamental to this improvement in health has been the diminution of poverty, for most public health measures are expensive. The peoples of the developing countries fall sick and sometimes die from infections that are virtually unknown in affluent countries.

Britain. Public health services in Britain are organized locally under the National Health Service. The medical officer of health is employed by the local council and is the adviser in health matters. The larger councils employ a number of mostly full-time medical officers; in some rural areas, a general practitioner may be employed part-time as medical officer of health.

Medical officer of health

The medical officer has various statutory powers conferred by acts of Parliament, regulations and orders, such as food and drugs acts, milk and dairies regulations, and factories acts. He supervises the work of sanitary inspectors in the control of health nuisances. The compulsorily notifiable infectious diseases are reported to him, and he takes appropriate action. Other concerns of the medical officer include those involved with the work of the district nurse, who carries out nursing duties in the home, and the health visitor, who gives advice on health matters, especially to the mothers of small babies. He has other duties in connection with infant welfare clinics, crèches, day and residential nurseries, the examination of schoolchildren, child guidance clinics, foster homes, factories, problem families, and the care of the aged and the handicapped.

United States. Federal, state, county, and city governments all have public health functions. Under the U.S. Department of Health and Human Services is the Public Health Service, headed by an assistant secretary for health and the surgeon general. State health departments are headed by a commissioner of health, usually a physician, who is often in the governor's cabinet. He usually has a board of health that adopts health regulations and holds hearings on their alleged violations. A state's public health code is the foundation on which all county and city health regulations must be based. A city health department may be independent of its surrounding county health department, or there may be a combined city-county health department. The physicians of the local health departments are usually called health officers, though occasionally people with this title are not physicians. The larger departments may have a public health director, a district health director, or a regional health director.

The minimal complement of a local health department is a health officer, a public health nurse, a sanitation expert, and a clerk who is also a registrar of vital statistics. There may also be sanitation personnel, nutritionists, social workers, laboratory technicians, and others.

Japan. Japan's Ministry of Health and Welfare directs public health programs at the national level, maintaining close coordination among the fields of preventive

medicine, medical care, and welfare and health insurance. The departments of health of the prefectures and of the largest municipalities operate health centres. The integrated community health programs of the centres encompass maternal and child health, communicable-disease control, health education, family planning, health statistics, food inspection, and environmental sanitation. Private physicians, through their local medical associations, help to formulate and execute particular public health programs needed by their localities.

Numerous laws are administered through the ministry's bureaus and agencies, which range from public health, environmental sanitation, and medical affairs to the children and families bureau. The various categories of institutions run by the ministry, in addition to the national hospitals, include research centres for cancer and leprosy, homes for the blind, rehabilitation centres for the physically handicapped, and port quarantine services.

Former Soviet Union. In the aftermath of the dissolution of the Soviet Union, responsibility for public health fell to the governments of the successor countries.

The public health services for the U.S.S.R. as a whole were directed by the Ministry of Health. The ministry, through the 15 union republic ministries of health, directed all medical institutions within its competence as well as the public health authorities and services throughout the country.

The administration was centralized, with little local autonomy. Each of the 15 republics had its own ministry of health, which was responsible for carrying out the plans and decisions established by the U.S.S.R. Ministry of Health. Each republic was divided into *oblasti,* or provinces, which had departments of health directly responsible to the republic ministry of health. Each *oblast,* in turn, had *rayony* (municipalities), which have their own health departments accountable to the *oblast* health department. Finally, each *rayon* was subdivided into smaller *uchastoki* (districts).

In most rural *rayony* the responsibility for public health lay with the chief physician, who was also medical director of the central *rayon* hospital. This system ensured unity of public health administration and implementation of the principle of planned development. Other health personnel included nurses, feldshers, and midwives.

For more information on the history, organization, and progress of public health, see below.

Military practice. The medical services of armies, navies, and air forces are geared to war. During campaigns the first requirement is the prevention of sickness. In all wars before the 20th century, many more combatants died of disease than of wounds. And even in World War II and wars thereafter, although few died of disease, vast numbers became casualties from disease.

Military prevention of sickness

The main means of preventing sickness are the provision of adequate food and pure water, thus eliminating starvation, avitaminosis, and dysentery and other bowel infections, which used to be particular scourges of armies; the provision of proper clothing and other means of protection from the weather; the elimination from the service of those likely to fall sick; the use of vaccination and suppressive drugs to prevent various infections, such as typhoid and malaria; and education in hygiene and in the prevention of sexually transmitted diseases, a particular problem in the services. In addition, the maintenance of high morale has a striking effect on casualty rates, for, when morale is poor, soldiers are likely to suffer psychiatric breakdowns, and malingering is more prevalent.

The medical branch may provide advice about disease prevention, but the actual execution of this advice is through the ordinary chains of command. It is the duty of the military, not of the medical, officer to ensure that the troops obey orders not to drink infected water and to take tablets to suppress malaria.

Army medical organization. The medical doctor of first contact to the soldier in the armies of developed countries is usually an officer in the medical corps. In peacetime the doctor sees the sick and has functions similar to those of the general practitioner, prescribing drugs and dressings, and there may be a sick bay where slightly sick soldiers can remain for a few days. The doctor is usually assisted by trained nurses and corpsmen. If a further medical opinion is required, the patient can be referred to a specialist at a military or civilian hospital.

Dealing with the wounded

In a war zone, medical officers have an aid post where, with the help of corpsmen, they apply first aid to the walking wounded and to the more seriously wounded who are brought in. The casualties are evacuated as quickly as possible by field ambulances or helicopters. At a company station, medical officers and medical corpsmen may provide further treatment before patients are evacuated to the main dressing station at the field ambulance headquarters, where a surgeon may perform emergency operations. Thereafter, evacuation may be to casualty clearing stations, to advanced hospitals, or to base hospitals. Air evacuation is widely used.

In peacetime most of the intermediate medical units exist only in skeleton form; the active units are at the battalion and hospital level. When physicians join the medical corps, they may join with specialist qualifications, or they may obtain such qualifications while in the army. A feature of army medicine is promotion to administrative positions. The commanding officer of a hospital and the medical officer at headquarters may have no contacts with actual patients.

Although medical officers in peacetime have some choice of the kind of work they will do, they are in a chain of command and are subject to military discipline. When dealing with patients, however, they are in a special position; they cannot be ordered by a superior officer to give some treatment or take other action that they believe is wrong. Medical officers also do not bear or use arms unless their patients are being attacked.

Medical organization in the navy

Naval and air force medicine. Naval medical services are run on lines similar to those of the army. Junior medical officers are attached to ships or to shore stations and deal with most cases of sickness in their units. When at sea, medical officers have an exceptional degree of responsibility in that they work alone, unless they are on a very large ship. In peacetime, only the larger ships carry a medical officer; in wartime, destroyers and other small craft may also carry medical officers. Serious cases go to either a shore-based hospital or a hospital ship.

Flying has many medical repercussions. Cold, lack of oxygen, and changes of direction at high speed all have important effects on bodily and mental functions. Armies and air forces may share the same medical services.

A developing field is aerospace medicine. This involves medical problems that were not experienced before spaceflight, for the main reason that humans in space are not under the influence of gravity, a condition that has profound physiological effects.

CLINICAL RESEARCH

The remarkable developments in medicine that have been brought about in the 20th century, especially since World War II, have been based on research either in the basic sciences related to medicine or in the clinical field. Advances in the use of radiation, nuclear energy, and space research have played an important part in this progress. Some laypersons often think of research as taking place only in sophisticated laboratories or highly specialized institutions where work is devoted to scientific advances that may or may not be applicable to medical practice. This notion, however, ignores the clinical research that takes place on a day-to-day basis in hospitals and doctors' offices.

Abandonment of remedies of the past

Historical notes. Although the most spectacular changes in the medical scene during the 20th century, and the most widely heralded, have been the development of potent drugs and elaborate operations, another striking change has been the abandonment of most of the remedies of the past. In the mid-19th century, persons ill with numerous maladies were starved (partially or completely), bled, purged, cupped (by applying a tight-fitting vessel filled with steam to some part and then cooling the vessel), and rested, perhaps for months or even years. Much more recently they were prescribed various restricted diets and were routinely kept in bed for weeks after abdominal operations, for many weeks or months when their hearts were

thought to be affected, and for many months or years with tuberculosis. The abandonment of these measures may not be thought of as involving research, but the physician who first encouraged persons who had peptic ulcers to eat normally (rather than to live on the customary bland foods) and the physician who first got his patients out of bed a week or two after they had had minor coronary thrombosis (rather than insisting on a minimum of six weeks of strict bed rest) were as much doing research as is the physician who first tries out a new drug on a patient. This research, by observing what happens when remedies are abandoned, has been of inestimable value, and the need for it has not passed.

Clinical observation. Much of the investigative clinical field work undertaken in the present day requires only relatively simple laboratory facilities because it is observational rather than experimental in character. A feature of much contemporary medical research is that it requires the collaboration of a number of persons, perhaps not all of them doctors. Despite the advancing technology, there is much to be learned simply from the observation and analysis of the natural history of disease processes as they begin to affect patients, pursue their course, and end, either in their resolution or by the death of the patient. Such studies may be suitably undertaken by physicians working in their offices who are in a better position than doctors working only in hospitals to observe the whole course of an illness. Disease rarely begins in a hospital and usually does not end there. It is notable, however, that observational research is subject to many limitations and pitfalls of interpretation, even when it is carefully planned and meticulously carried out.

Drug research. The administration of any medicament, especially a new drug, to a patient is fundamentally an experiment: so is a surgical operation, particularly if it involves a modification to an established technique or a completely new procedure. Concern for the patient, careful observation, accurate recording, and a detached mind are the keys to this kind of investigation, as indeed to all forms of clinical study. Because patients are individuals reacting to a situation in their own different ways, the data obtained in groups of patients may well require statistical analysis for their evaluation and validation.

New drug development

One of the striking characteristics in the medical field in the 20th century has been the development of new drugs, usually by pharmaceutical companies. Until the end of the 19th century, the discovery of new drugs was largely a matter of chance. It was in that period that Paul Ehrlich, the German scientist, began to lay down the principles for modern pharmaceutical research that made possible the development of a vast array of safe and effective drugs. Such benefits, however, bring with them their own disadvantages: it is estimated that as many as 30 percent of patients in, or admitted to, hospitals suffer from the adverse effect of drugs prescribed by a physician for their treatment (iatrogenic disease). Sometimes it is extremely difficult to determine whether a drug has been responsible for some disorder. An example of the difficulty is provided by the thalidomide disaster between 1959 and 1962. Only after numerous deformed babies had been born throughout the world did it become clear that thalidomide taken by the mother as a sedative had been responsible.

Hospital ethical committees

In hospitals where clinical research is carried out, ethical committees often consider each research project. If the committee believes that the risks are not justified, the project is rejected.

After a potentially useful chemical compound has been identified in the laboratory, it is extensively tested in animals, usually for a period of months or even years. Few drugs make it beyond this point. If the tests are satisfactory, the decision may be made for testing the drug in humans. It is this activity that forms the basis of much clinical research. In most countries the first step is the study of its effects in a small number of health volunteers. The response, effect on metabolism, and possible toxicity are carefully monitored and have to be completely satisfactory before the drug can be passed for further studies, namely with patients who have the disorder for which the drug is to be used. Tests are administered at first to a limited number of these patients to determine effectiveness, proper dosage, and possible adverse reactions. These searching studies are scrupulously controlled under stringent conditions. Larger groups of patients are subsequently involved to gain a wider sampling of the information. Finally, a full-scale clinical trial is set up. If the regulatory authority is satisfied about the drug's quality, safety, and efficacy, it receives a license to be produced. As the drug becomes more widely used, it eventually finds its proper place in therapeutic practice, a process that may take years.

The controlled clinical trial

An important step forward in clinical research was taken in the mid-20th century with the development of the controlled clinical trial. This sets out to compare two groups of patients, one of which has had some form of treatment that the other group has not. The testing of a new drug is a case in point: one group receives the drug, the other a product identical in appearance, but which is known to be inert—a so-called placebo. At the end of the trial, the results of which can be assessed in various ways, it can be determined whether or not the drug is effective and safe. By the same technique two treatments can be compared, for example a new drug against a more familiar one. Because individuals differ physiologically and psychologically, the allocation of patients between the two groups must be made in a random fashion; some method independent of human choice must be used so that such differences are distributed equally between the two groups.

In order to reduce bias and make the trial as objective as possible the double-blind technique is sometimes used. In this procedure, neither the doctor nor the patients know which of two treatments is being given. Despite such precautions the results of such trials can be prejudiced, so that rigorous statistical analysis is required. It is obvious that many ethical, not to say legal, considerations arise, and it is essential that all patients have given their informed consent to be included. Difficulties arise when patients are unconscious, mentally confused, or otherwise unable to give their informed consent. Children present a special difficulty because not all laws agree that parents can legally commit a child to an experimental procedure. Trials, and indeed all forms of clinical research that involve patients, must often be submitted to a committee set up locally to scrutinize each proposal.

Surgery. In drug research the essential steps are taken by the chemists who synthesize or isolate new drugs in the laboratory; clinicians play only a subsidiary part. In developing new surgical operations clinicians play a more important role, though laboratory scientists and others in the background may also contribute largely. Many new operations have been made possible by advances in anesthesia, and these in turn depend upon engineers who have devised machines and chemists who have produced new drugs. Other operations are made possible by new materials, such as the alloys and plastics that are used to make artificial hip and knee joints.

Whenever practicable, new operations are tried on animals before they are tried on patients. This practice is particularly relevant to organ transplants. Surgeons themselves—not experimental physiologists—transplanted kidneys, livers, and hearts in animals before attempting these procedures on patients. Experiments on animals are of limited value, however, because animals do not suffer from all of the same maladies as do humans.

Animal experimentation

Many other developments in modern surgical treatment rest on a firm basis of experimentation, often first in animals but also in humans; among them are renal dialysis (the artificial kidney), arterial bypass operations, embryo implantation, and exchange transfusions. These treatments are but a few of the more dramatic of a large range of therapeutic measures that have not only provided patients with new therapies but also have led to the acquisition of new knowledge of how the body works. Among the research projects of the late 20th century is that of gene transplantation, which has the potential of providing cures for cancer and other diseases.

SCREENING PROCEDURES

Developments in modern medical science have made it possible to detect morbid conditions before a person actu-

ally feels the effects of the condition. Examples are many: they include certain forms of cancer; high blood pressure; heart and lung disease; various familial and congenital conditions; disorders of metabolism, like diabetes; and acquired immune deficiency syndrome (AIDS). The consideration to be made in screening is whether or not such potential patients should be identified by periodic examinations. To do so is to imply that the subjects should be made aware of their condition and, second, that there are effective measures that can be taken to prevent their condition, if they test positive, from worsening. Such so-called specific screening procedures are costly since they involve large numbers of people. Screening may lead to a change in the life-style of many persons, but not all such moves have been shown in the long run to be fully effective. Although screening clinics may not be run by doctors, they are a factor of increasing importance in the preventive health service.

Periodic general medical examination of various sections of the population, business executives for example, is another way of identifying risk factors that, if not corrected, can lead to the development of overt disease.

Medical education

Goals of medical education

Medical education is directed toward imparting to persons seeking to become physicians the knowledge and skills required for the prevention and treatment of disease and also for developing the methods and objectives appropriate to the study of the still unknown factors that produce disease or favour well-being. Among the goals of medical education is the production of physicians sensitive to the health needs of their country, capable of ministering to those needs, and aware of the necessity of continuing their own education. It therefore follows that the plan of education, the medical curriculum, should not be the same in all countries. Although there may be basic elements common to all, the details should vary from place to place and from time to time. Whatever form the curriculum takes, ideally it will be flexible enough to allow modification as circumstances alter, medical knowledge grows, and needs change.

Attention in this article is focused primarily on general medical education.

HISTORY OF MEDICAL EDUCATION

Although it is difficult to identify the origin of medical education, authorities usually consider that it began with the ancient Greeks' method of rational inquiry, which introduced the practice of observation and reasoning regarding disease. Rational interpretation and discussion, it is theorized, led to teaching and thus to the formation of schools such as that at Cos, where the Greek physician Hippocrates is said to have taught in the 5th century BC and originated the oath that became a credo for practitioners through the ages.

Later, the Christian religion greatly contributed to both the learning and the teaching of medicine in the West because it favoured not only the protection and care of the sick but also the establishment of institutions where collections of sick people encouraged observation, analysis, and discussion among physicians by furnishing opportunities for comparison. Apprenticeship training in monastic infirmaries and hospitals dominated medical education during the early Middle Ages. A medical school in anything like its present form, however, did not evolve until the establishment of the one at Salerno in southern Italy between the 9th and 11th centuries. Even there teaching was by the apprentice system, but an attempt was made at systemization of the knowledge of the time, a series of health precepts was drawn up, and a form of registration to practice was approved by the Holy Roman emperor Frederick II. During the same period, medicine and medical education were flourishing in the Muslim world at such centres as Baghdad, Cairo, and Córdoba.

With the rise of the universities in Italy and later in Cracow, Prague, Paris, Oxford, and elsewhere in western Europe, the teachers of medicine were in some measure drawn away from the life of the hospitals and were offered the attractions and prestige of university professorships and lectureships. As a result, the study of medicine led more often to a familiarity with theories about disease than with actual sick persons. However, the establishment in 1518 of the Royal College of Physicians of London, which came about largely through the energies of Thomas Linacre, produced a system that called for examination of medical practitioners. The discovery of the circulation of the blood by William Harvey provided a stimulus to the scientific study of the processes of the body, bringing some deemphasis to the tradition of theory and doctrine.

The Royal College of Physicians

Gradually, in the 17th and 18th centuries, the value of hospital experience and the training of the students' sight, hearing, and touch in studying disease were reasserted. In Europe, medical education began slowly to assume its modern character in the application of an increasing knowledge of natural science to the actual care of patients. There was also encouragement of the systematic study of anatomy, botany, and chemistry, sciences at that time considered to be the basis of medicine. The return to the bedside aided the hospitals in their long evolution from dwelling places of the poor, the diseased, and the infirm, maintained by charity and staffed usually by religious orders, into relatively well-equipped, well-staffed, efficient establishments that became available to the entire community and were maintained by private or public expense.

It was not until the mid-19th century, however, that an ordered pattern of science-oriented teaching was established. This pattern, the traditional medical curriculum, was generally adopted by Western medical schools. It was based upon teaching, where the student mostly listens, rather than learning, where the student is more investigative. The clinical component, largely confined to hospitals (charitable institutions staffed by unpaid consultants), was not well organized. The new direction in medical education was aided in Britain by the passage of the Medical Act of 1858, which has been termed the most important event in British medicine. It established the General Medical Council, which thenceforth controlled admission to the medical register and thus had great powers over medical education and examinations. Further interest in medicine grew from these advances, which opened the way for the discoveries of Louis Pasteur, which showed the relation of microorganisms to certain diseases, Joseph Lister's application of Pasteur's concepts to surgery, and the studies of Rudolf Virchow and Robert Koch in cellular pathology and bacteriology.

Advances at Johns Hopkins Medical School

In the United States, medical education was greatly influenced by the example set in 1893 by the Johns Hopkins Medical School in Baltimore. It admitted only college graduates with a year's training in the natural sciences. Its clinical work was superior because the school was supplemented by the Johns Hopkins Hospital, created expressly for teaching and research carried on by members of the medical faculty. The adequacy of medical schools in the United States was improved after the Carnegie Foundation for the Advancement of Teaching published in 1910 a report by the educator Abraham Flexner. In the report, which had an immediate impact, he pointed out that medical education actually is a form of education rather than a mysterious process of professional initiation or apprenticeship. As such, it needs an academic staff, working full-time in their departments, whose whole responsibility is to their professed subject and to the students studying it. Medical education, the report further stated, needs laboratories, libraries, teaching rooms, and ready access to a large hospital, the administration of which should reflect the presence and influence of the academic staff. Thus the nature of the teaching hospital was also influenced. Aided by the General Education Board, the Rockefeller Foundation, and a large number of private donors, U.S. and Canadian medical education was characterized by substantial improvements from 1913 to 1929 in such matters as were stressed in the Flexner report.

MODERN PATTERNS OF MEDICAL EDUCATION

As medical education developed after the Flexner report was published, the distinctive feature was the thorough-

ness with which theoretical and scientific knowledge were fused with what experience teaches in the practical responsibility of taking care of human beings. Medical education eventually developed into a process that involved four generally recognized stages: premedical, undergraduate, postgraduate, and continuing education.

Premedical education and admission to medical school. In the United States, Britain, and the Commonwealth countries, generally, medical schools are inclined to limit the number of students admitted so as to increase the opportunities for each student. In western Europe, South America, and most other countries, no exact limitation of numbers of students is in effect, though there is a trend toward such limitation in some of the western European schools. Some medical schools in North America have developed ratios of teaching staff to students as high as 1 to 1 or 1 to 2, in contrast with 1 teacher to 20 or even 100 students in certain universities in other countries. The number of students applying to medical school greatly exceeds the number finally selected in most countries.

Limitation of number of students

Requirements to enter medical school, of course, vary from country to country, and in some countries, such as the United States, from university to university. Generally speaking, in Western universities, there is a requirement for a specified number of years of undergraduate work and passing of a test, possibly state regulated, and a transcript of grades. In the United States entry into medical school is highly competitive, especially in the more prestigious universities. Stanford University, for instance, accepts only about 5 percent of its applicants. Most U.S. schools require the applicant to take the Medical College Admission Test, which measures aptitude in medically related subjects. Other requirements may include letters of recommendation and a personal interview. Many U.S. institutions require a bachelor's degree or its equivalent from an undergraduate school. A specific minimum grade point average is not required, but most students entering medical school have between an A and a B average.

The premedical courses required in most countries emphasize physics, chemistry, and biology. These are required in order to make it possible to present subsequently courses in anatomy, physiology, biochemistry, and pharmacology with precision and economy of time to students prepared in scientific method and content. Each of the required courses includes laboratory periods throughout the full academic year. Student familiarity with the use of instruments and laboratory procedures tends to vary widely from country to country, however.

Undergraduate education. The medical curriculum also varies from country to country. Most U.S. curriculums cover four years; in Britain five years is normal. The early part of the medical school program is sometimes called the preclinical phase. Medical schools usually begin their work with the study of the structure of the body and its formation: anatomy, histology, and embryology. Concurrently, or soon thereafter, come studies related to function—*i.e.*, physiology, biochemistry, pharmacology, and, in many schools, biophysics. After the microscopic study of normal tissues (histology) has begun, the student is usually introduced to pathological anatomy, bacteriology, immunology, parasitology—in short, to the agents of disease and the changes that they cause in the structure and function of the tissues. Courses in medical psychology, biostatistics, public health, alcoholism, biomedical engineering, emergency medicine, ethical problems, and other less traditional courses are becoming more common in the first years of the medical curriculum.

The clinical years

The two or more clinical years of an effective curriculum are characterized by active student participation in small group conferences and discussions, a decrease in the number of formal lectures, and an increase in the amount of contact with patients in teaching hospitals and clinics.

Clinical work begins with general medicine and surgery and goes on to include the major clinical specialties, including obstetrics and gynecology, pediatrics, disorders of the eye, ear, nose, throat, and skin, and psychiatry. The student works in the hospital's outpatient, emergency, and radiology departments, diagnostic laboratories, and surgical theatres. The student also studies sciences closely related to medicine, such as pathology, microbiology, hematology, immunology, and clinical chemistry and becomes familiar with epidemiology and the methods of community medicine. Some knowledge of forensic (legal) medicine is also expected. During the clinical curriculum many students have an opportunity to pursue a particular interest of their own or to enlarge their clinical experience by working in a different environment, perhaps even in a foreign country—the so-called elective period. Most students find clinical work demanding, usually requiring long hours of continuous duty and personal commitment.

In the United States after satisfactory completion of a course of study in an accredited medical school the degree of doctor of medicine (M.D.) or doctor of osteopathy (D.O.) is conferred. In Britain and some of the other Commonwealth countries the academic degree conferred after undergraduate studies are completed is bachelor of medicine and of surgery (or chirurgery), M.B., B.S. or M.B., CHb. Only after further study is the M.D. degree given. Similar degrees are conferred in other countries, although they are not always of the same status.

Postgraduate education. On completion of medical school, the physician usually seeks graduate training and experience in a hospital under the supervision of competent clinicians and other teachers. In Britain a year of resident hospital work is required after qualification and before admission to the medical register. In North America, the first year of such training has been known as an internship, but it is no longer distinguished in most hospitals from the total postgraduate period, called residency. After the first year physicians usually seek further graduate education and training to qualify themselves as specialists or to fulfill requirements for a higher academic degree. Physicians seeking special postgraduate degrees are sometimes called fellows.

Internship and residency

Continuing education. The process by which physicians keep themselves up-to-date is called continuing education. It consists of courses and training opportunities of from a few days to several months in duration, designed to enable physicians to learn of new developments within their special areas of concern. Physicians also attend medical and scientific meetings, national and international conferences, discussion groups, and clinical meetings, and they read medical journals and other materials, all of which serve to keep them aware of progress in their chosen field. Although continuing education is not a formal process, organizations designed to promote continuing education have become common. In the United States the Accreditation Council for Continuing Medical Education was formed in 1985, and some certifying boards of medical specialties have stringent requirements for continuing education.

The quality of medical education is supervised in many countries by councils appointed by the profession as a whole. In the United States these include the Council on Medical Education and the Liaison Committee on Medical Education, both affiliates of the American Medical Association, and the American Osteopathic Association. In Britain the statutory body is the General Medical Council, most of whose members are from the profession, although only a minority of the members are appointed by it. In other countries medical education may be regulated by an office or ministry of public instruction with, in some cases, the help of special professional councils.

Medical school faculty. As applied to clinical teachers the term full-time originally implied an educational ideal: that a clinician's salary from a university should be large enough to relieve him of any reason for seeing private patients for the sake of supplementing his salary by professional fees. Full-time came to be applied, however, to a variety of modifications; it could mean that a clinical professor might supplement his salary as a teacher up to a defined maximum, might see private patients only at his hospital office, or might see such patients only a certain number of hours per week. The intent of full-time has always been to place the teacher's capacities and strength entirely at the service of his students and the patients entrusted to his care as a teacher and investigator.

Courses in the medical sciences have commonly followed the formula of three hours of lectures and six to nine

hours of laboratory work per week for a three-, six-, or nine-month course. Instruction in clinical subjects, though retaining the formal lecture, have tended to diminish the time and emphasis allowed to lectures in favour of experience with and attendance on patients. Nonetheless, the level of lecturing and formal presentation remains high in some countries.

REQUIREMENTS FOR PRACTICE

Licensure to practice

Graduation from medical school and postgraduate work does not always allow the physician to practice. In the United States, licensure to practice medicine is controlled by boards of licensure in each state. The boards set and conduct examinations of applicants to practice within the state, and they examine the credentials of applicants who want licenses earned in other states to be accepted in lieu of examination. The National Board of Medical Examiners holds examinations leading to a degree that is acceptable to most state boards. National laws regulating professional practice cannot be enacted in the United States. In Canada the Medical Council of Canada conducts examinations and enrolls successful candidates on the Canadian medical register, which the provincial governments accept as the main requirement for licensure. In Britain the medical register is kept by the General Medical Council, which supervises the licensing bodies; unregistered practice, however, is not illegal. In some European countries graduation from a state-controlled university or medical school in effect serves as a license to practice; the same is true for Japan. (For further details of licensure, see below *Legal aspects of medicine*.)

ECONOMIC ASPECTS

Sources of medical school income

The income of a medical school is derived from four principal sources: (1) tuition and fees, (2) endowment income or appropriation from the government (taxation), (3) gifts from private sources, and (4) donation of teachers' services. Tuition or student fees are large in most English-speaking countries (except in U.S. state universities) and relatively small throughout the rest of the world. Tuition in most American schools, however, rarely makes up more than a small part of total operating expenses. The total cost of maintaining a medical school, if prorated among the students, would produce a figure many times greater than the tuition or other charges paid by each student. The costs of operating medical schools in the United States increased by about 30 times between the late 1950s and the mid-1980s.

The expenses of medical education fall into two groups: those of the instruction given in the medical sciences and those connected with hospital teaching. In the medical sciences the costs of building maintenance, laboratory equipment and supplies, research expenses, salaries of teachers, and wages of employees are heavy but comparable to those in other departments of a university. In the clinical subjects all expenses in connection with the care of patients usually are considered as hospital expenses and are not carried on the medical school budget, which is normally reserved for the expenses of teaching and research. Here the heavy expenses are salaries of clinical teachers and the cost of studying cases of illness with a thoroughness appropriate to their use as teaching material.

To a considerable degree in free-market countries, the cost of securing an adequate medical education has tended to exclude the student whose family cannot contribute a large share of tuition and living expenses for four to 10 years. This difficulty is offset in some medical schools by loan funds and scholarships, but these aids are commonly offered only in the second or subsequent years. In Britain scholarships and maintenance grants are available through state and local educational authority funds, so that an individual can secure a medical education even though the parents may not be able to afford its cost.

SCIENTIFIC AND INTERNATIONAL ASPECTS

Medical education has the double task of passing on to students what is known and of attacking what is still unknown. The cost of medical research is borne by only a few; the benefits are shared by many. There are countries whose citizens are too poor to support physicians or to use them, countries that can support a few physicians but are too poor to maintain a good medical school, countries that can maintain medical schools where what is known can be taught but where no research can be carried out, and a few countries in which teaching and research in medicine can be carried on to the great advantage of the world at large.

A medical school having close geographical as well as administrative relationships with the rest of the university of which it forms a part usually profits by this intimate and easy contact. Medicine cannot wisely be separated from the biological sciences, and it continues to gain immensely from chemistry, physics, mathematics, and psychology, as well as from modern technology. The social sciences contribute by making physicians aware of the need for better distribution of medical care. Contact with teachers and the advancing knowledge in other faculties also may have a corollary effect in advancing medicine.

WHO

With the development of the World Health Organization (WHO) and the World Medical Association after World War II, there has been increasing international interest in medical education. WHO conducts a regular program for aiding countries in the development and expansion of their educational facilities. World War II showed the advantages and economy derived from satisfactory systems of medical education: defects and diseases were more widely and accurately detected among recruits than ever before, health and morale were effectively maintained among combatants, and disease and battle injuries were effectively treated. MAJOR MEDICAL INSTITUTIONS

Hospitals

A hospital is an institution that is built, staffed, and equipped for the identification (diagnosis) of disease; for the treatment, both medical and surgical, of the sick and the injured; and for their housing during this process. The modern hospital also often serves as a centre for investigation and for teaching. To better serve the wide-ranging needs of the community, the modern hospital has often developed outpatient facilities, as well as emergency, psychiatric, and rehabilitation services.

Hospitals have long existed in every civilized country. The developing countries, which contain a large proportion of the world's population, do not have enough hospitals, equipment, and trained staff, and, by the standards of the industrialized countries, the hospitals that do exist are poorly equipped to handle the volume of persons who need care. These persons, then, do not always receive the benefits of modern medicine, public health measures, or hospital care, and they generally have lower life expectancies.

In the developed countries the hospital as an institution is becoming more complex as modern technology increases the range of diagnostic capabilities and expands the possibilities for treatment. As a result of the greater range of services and the more involved treatment and surgery available, the ratio of staff to patient has increased and a more highly trained staff is required. During recent years a combination of medicine and engineering has produced a vast array of new instrumentation, much of which requires a hospital setting for its use. Hospitals thus are becoming more expensive to run, and health service administrators are increasingly concerned with the question of cost-effectiveness.

HISTORY OF HOSPITALS

As early as 4000 BC religions identified certain of their deities with healing. The temples of Saturn, and later of

Hospitals in antiquity

Asclepius in Asia Minor, were recognized as healing centres. Brahmanic hospitals were established in Sri Lanka as early as 431 BC, and King Aśoka established a chain of hospitals in Hindustān about 230 BC. Around 100 BC the Romans established hospitals (*valetudinaria*) for the treatment of their sick and injured soldiers; their care was important because it was upon the integrity of the legions that the power of Rome was based.

It can be said, however, that the modern concept of a hospital dates from AD 331 when Constantine, having been converted to Christianity, abolished all pagan hospitals and thus created the opportunity for a new start. Until that time disease had isolated the sufferer from the community. The Christian tradition emphasized the close relationship of the sufferer to his fellow man, upon whom rested the obligation for care. Illness thus became a matter for the Christian church.

Around AD 370 St. Basil of Caesarea established a religious foundation in Cappadocia that included a hospital, an isolation unit for those suffering from leprosy, and buildings to house the poor, the elderly, and the sick. Following this example similar hospitals were later built in the eastern part of the Roman Empire. Another notable foundation was that of St. Benedict at Monte Cassino, founded early in the 6th century, where the care of the sick was placed above and before every other Christian duty. It was from this beginning that one of the first medical schools in Europe ultimately grew at Salerno and was of high repute by the 11th century. This example led to the establishment of similar monastic infirmaries in the western part of the empire.

The Hôtel-Dieu of Lyon was opened in 542 and the Hôtel-Dieu of Paris in 660. In these hospitals more attention was given to the well-being of the patient's soul than to curing bodily ailments. The manner in which monks cared for their own sick became a model for the laity. The monasteries had an *infirmitorium*, a place to which their sick were taken for treatment. The monasteries had a pharmacy and frequently a garden with medicinal plants. In addition to caring for sick monks, the monasteries opened their doors to pilgrims and to other travelers.

Religion continued to be the dominant influence in the establishment of hospitals during the Middle Ages. The growth of hospitals accelerated during the Crusades, which began at the end of the 11th century. Pestilence and disease were more potent enemies than the Saracens in defeating the crusaders. Military hospitals came into being along the traveled routes; the Knights Hospitalers of the Order of St. John in 1099 established in the Holy Land a hospital that could care for some 2,000 patients. It is said to have been especially concerned with eye disease, and may have been the first of the specialized hospitals. This order has survived through the centuries as the St. John's Ambulance Corps.

Throughout the Middle Ages, but notably in the 12th century, the number of hospitals grew rapidly in Europe. The Arabs established hospitals in Baghdad and Damascus and in Córdoba in Spain. Arab hospitals were notable for the fact that they admitted patients regardless of religious belief, race, or social order. The Hospital of the Holy Ghost, founded in 1145 at Montpellier in France, established a high reputation and later became one of the most important centres in Europe for the training of doctors. By far the greater number of hospitals established during the Middle Ages, however, were monastic institutions under the Benedictines, who are credited with having founded more than 2,000.

The Middle Ages also saw the beginnings of support for hospital-like institutions by secular authorities. Toward the end of the 15th century many cities and towns supported some kind of institutional health care: it has been said that in England there were no less than 200 such establishments that met a growing social need. This gradual transfer of responsibility for institutional health care from the church to civil authorities continued in Europe after the dissolution of the monasteries in 1540 by Henry VIII, which put an end to hospital building in England for some 200 years.

The loss of monastic hospitals in England caused the secular authorities to provide for the sick, the injured, and the handicapped, thus laying the foundation for the voluntary hospital movement. The first voluntary hospital in England was probably established in 1718 by Huguenots from France and was closely followed by the foundation of such London hospitals as the Westminster Hospital in 1719, Guy's Hospital in 1724, and the London Hospital in 1740. Between 1736 and 1787 hospitals were established outside London in at least 18 cities. The initiative spread to Scotland where the first voluntary hospital, the Little Hospital, was opened in Edinburgh in 1729.

Early hospitals in North America

The first hospital in North America was built in Mexico City in 1524 by Cortés; the structure still stands. The French established a hospital in Canada in 1639 at Quebec city, the Hôtel-Dieu du Précieux Sang, which is still in operation although not at its original location. In 1644 Jeanne Mance, a French noblewoman, built a hospital of ax-hewn logs on the island of Montreal; this was the beginning of the Hôtel-Dieu de St. Joseph, out of which grew the order of the Sisters of St. Joseph, now considered to be the oldest nursing group organized in North America. The first hospital in the territory of the present-day United States is said to have been a hospital for soldiers on Manhattan Island, established in 1663.

The early hospitals were primarily almshouses, one of the first of which was established by William Penn in Philadelphia in 1713. The first incorporated hospital in America was the Pennsylvania Hospital, in Philadelphia, which obtained a charter from the crown in 1751.

THE MODERN HOSPITAL

Hospitals may be compared and classified in various ways: by ownership and control, by type of service rendered, by length of stay, by size, or by facilities and organization provided. Terms in general use include the general as distinct from the special hospital, the short-stay hospital, and the long-term hospital.

Comparison. Hospitals may be compared by the number of beds they contain. Modern hospitals tend to be small, rarely exceeding 800 beds, which is thought to be the largest number that can be governed satisfactorily from a single administrative unit, yet not too large to retain a corporate unity.

Another index is the average bed-occupancy, that is, the percentage of available beds actually occupied per day or per month. In Europe bed-occupancy may be higher in the cold winter months, which bring more respiratory disease. In developing countries the bed-occupancy is often more than 100 percent: that is to say there are more patients in the hospital than there are beds for them.

The amount of time that a patient spends in a hospital bed, the bed-stay, is another important index and depends on the nature of the hospital. In an acute-care hospital the bed-occupancy will be low. In hospitals catering to the more chronically ill, the average bed-stay probably will be higher. There are even significant variations between units in the same hospital doing the same kind of work. In hospitals in developing countries, the average bed-stay is much shorter than in Europe.

Ownership, control, and financing. *Ownership and control.* In most countries outside of North America nearly all hospitals are owned and operated by the government. In Great Britain, except for a small number run by religious orders or serving special groups, most hospitals are within the National Health Service. The local hospital management committee answers directly to the regional hospital board and ultimately to the Department of Health and Social Security. In the United States and Canada most hospitals are nonprofit and are neither owned nor operated by governmental agencies. Many of them are associated with universities; others were founded by religious groups or by public-spirited individuals. Mental hospitals traditionally have been the responsibility of the state governments, while military and veterans hospitals have been provided by the federal government. In addition, there are a number of municipal and county general hospitals.

Financing. Almost universally, hospital construction costs are met at least in some part by governmental contributions. Operating costs are taken care of in a variety

of ways. Ultimately, a substantial portion of the expenses not covered by private endowments or gifts is met by contributions from the general funds of some unit of government or out of funds collected by insurance carriers from subscribers. In countries in which hospital insurance is not universal or its coverage is incomplete, some of the operating costs are met by charges on uninsured or inadequately insured patients.

Carriers of hospital insurance

The carriers of the hospital insurance in a particular country may be governmental agencies, private corporations or agencies, or both. In Britain, for example, under the National Insurance Act, the government is the carrier. All persons who have reached the minimum school-leaving age and are not full-time students, beyond the age of retirement, in prison, or receivers of benefits from the insurance and who do not have less than a certain minimum income are contributors under the plan whether employed by others, self-employed, or nonemployed. Employers also contribute.

In the United States persons who are employed by others or are self-employed make compulsory contributions toward a form of national hospital insurance, Medicare, which pays a large portion of the hospital costs of persons at the age of 65 or over. Employers then make matching payments. A majority of the persons ineligible, by reason of age, for benefits under the Medicare program are enrolled in some other form of hospital insurance, such as one of the plans offered by the commercial insurance companies or one of the independent plans, including community and community-controlled plans and those operated by unions, employers, welfare funds, and private medical clinics.

In the United States, even with federal participation under Medicare and Medicaid (a program for persons under 65 who are unable to pay), the payment for health care services on an insurance basis, either voluntary or governmental, is considerably less advanced than it is in many other parts of the world. In Europe, particularly, the financial support of services in hospitals tends to be much more collectivized. Less than 10 percent of the costs of hospital operation in Europe is covered by payments made directly by patients. Details vary somewhat from country to country: in the United Kingdom, for example, the funds for total hospital operation are appropriated by the Ministry of Social Security to each regional hospital board, which in turn distributes them to the local hospital groups. In Sweden, however, approximately 90 percent of hospital operating costs are provided by local or provincial units of government from public revenue; the remaining 10 percent of the costs comes from payments made by insurance funds on behalf of the patient. In general, in the majority of European countries, hospital operating costs are paid out of insurance funds; such is the case in France, Italy, The Netherlands, Norway, and elsewhere.

The general hospital. General hospitals are general in the sense that they admit all types of medical and surgical cases, and they concentrate on patients with acute illness needing relatively short-term care. A community general hospital with about 200 beds has an organized medical staff, a professional nursing staff, and diagnostic equipment. In addition to the essential services relating to patient care, it has a pharmacy, a laboratory, X-ray and physical therapy departments, possibly a maternity division (ordinarily including a nursery and a delivery room), operating rooms, recovery rooms, an outpatient department, and an emergency department.

The community general hospital

In a somewhat larger hospital there may be additional facilities: dental services, a nursery for premature infants, an organ bank for use in transplantation, a department of renal dialysis (removal of wastes from the blood by passing it through semipermeable membranes, as in the artificial kidney), equipment for inhalation therapy, an intensive-care unit, a volunteer-services department, and, possibly, a home-care program. The complexity of the general hospital, then, reflects the advances made after World War II, including the use of antibiotics, a vast new array of laboratory procedures, new surgical techniques, new materials and equipment for radiation therapy, and an increased emphasis on physical therapy and rehabilitation.

The legally constituted governing body of the hospital, with full responsibility for the conduct and efficient management of the hospital, is usually a hospital board. The board establishes policy and, on the advice of a medical advisory board, appoints a medical staff and an administrator. It exercises control over expenditures and has the responsibility for maintaining professional standards.

The administrator is the chief executive officer of the hospital and is responsible to the board. In a large hospital there are many separate departments, each of which is controlled by a department head. The largest department in any hospital is nursing, followed by the dietary department and housekeeping. Other departments that are important to the functioning of the hospital include laundry, engineering, stores, purchasing, accounting, pharmacy, physical therapy, social service, pathology, X-ray, and medical records.

Organization of medical staff

The medical staff is organized into such departments as surgery, medicine, obstetrics, and pediatrics. The degree of departmentalization of the medical staff depends on the specialization of its members and not primarily on the size of the hospital, although there is usually some correlation between the two. The chiefs of the medical-staff departments, along with the chiefs of radiology and pathology, make up the medical advisory board, which usually holds monthly meetings on medical-administrative matters. The professional work of the individual staff members is reviewed by medical-staff committees. In a large hospital the committees may report to the medical advisory board; in a smaller hospital, to the medical staff directly, at regular staff meetings.

General hospitals often also have a formal or informal role as teaching institutions. When formally designed as such, teaching hospitals are affiliated with undergraduate and postgraduate medical education at a university, and they provide up-to-date and often specialized therapeutic measures and facilities unavailable elsewhere in the region. As teaching hospitals have become more specialized, general hospitals have become more involved in providing general clinical training to medical students.

Specialized health- and medical-care facilities. Hospitals that specialize in one type of illness or one type of patient can be found in Europe and in North America, although, except in large university centres where postgraduate teaching is carried out on a large scale, the special hospital is increasingly becoming a department of the general hospital. Changing conditions or modes of treatment have lessened the need or reduced the number of some types of specialized institutions; this may be seen in the cases of tuberculosis, leprosy, and mental hospitals.

Tuberculosis and leprosy hospitals. Between 1880 and 1940 tuberculosis hospitals provided rest, relaxation, special diets, and fresh air, and even if the tuberculosis was in an early stage, a stay of more than two years was thought necessary to effect a healing of the disease; a permanent cure was not considered entirely feasible. Today the use of antibiotics, along with advances in chest surgery and routine X-ray programs, has meant that the treatment of tuberculosis need not be carried out in a specialized facility.

Leprosy has been known for centuries to be contagious. Lazar houses were established throughout Europe in the Middle Ages to isolate those with leprosy, at that time a common disease, from the community. In the 14th century there may have been some 7,000 leper houses in France alone, and some of the earliest hospitals in England were established for lepers. Although it is now rare in Europe, leprosy is still common in many parts of the world. The purpose of the modern leprosarium is not so much isolation as it is treatment. The chronic form of the disease is treated by surgical correction of deformities, occupational therapy, rehabilitation, and sheltered living in associated villages. Acute leprosy is treated in general hospitals, clinics, and dispensaries.

Mental hospitals. Psychiatric patients traditionally have been housed in long-stay mental hospitals, formerly called asylums, although the majority of large general hospitals now have a psychiatric unit. In the past few decades the hospital stay of many persons with chronic mental disease has been shortened by modern medication and better

Changes in treatment of mental patients

understanding on the part of the public. Mental patients often may participate in many activities, first within the hospital setting and later in the community, either with trial visits at home or with placement of selected patients in foster homes. Effort is now made with appropriate medication and the judicious use of the support services to get the patient home and in the care of the family. Even those mentally handicapped persons who require custodial care are no longer isolated from contact with their relatives and friends.

Long-stay institutions. Historically the long-stay institution was a place for the elderly, the infirm, and those with chronic irreversible and disabling disorders, especially if the patients were indigent. Medical and nursing care was minimal. Today the long-stay hospital has a more active role in health care. Many are well staffed and well equipped to help a patient prepare to live at home or with a member of the family. Long-stay hospitals represent a significant extension of the hospital health-care system, helping to conserve expensive facilities for the acutely ill and improving the prospects of the chronically disabled.

Private hospitals. Throughout Europe, as well as in North America, Australia, and New Zealand, there are small private hospitals, often called nursing homes in Britain, many of which until recently were able to provide little more than accommodation and simple nursing, the patient being under the care of a general practitioner or of a visiting consultant. Medical practice in the towns of developing countries is characterized by a proliferation of many small private hospitals, usually owned by doctors, that have developed to meet the widespread need for hospital care not otherwise available.

Another method of providing health care in a hospital for those able to pay for it, both in industrial and developing countries, is the provision of a limited number of beds for private patients within a large general hospital otherwise financed to some degree by public funds. In the United Kingdom and, for example, in West Africa, these so-called amenity beds usually form part of the ward unit, the patient being required to pay for certain amenities such as a measure of privacy, unrestricted visiting, attractively served food, and a more liberal routine. Alternatively, many large general hospitals are able to offer much more costly accommodations in so-called private blocks—that is, in a part of the hospital specially designed and equipped for private patients. Patients in a private block pay a large portion of the total cost of their medical care, including that of surgery.

Private patients

More recent is the development of the wholly independent private hospital run by a company or business consortium. Many of these privately funded hospitals are able to provide most or all of the services of a general hospital, including constant medical care and a first-rate nursing service, although such facilities are costly.

The hospice. Historically a hospice was a guest house intended for pilgrims and was often closely connected with a monastery and supervised by monks. From the beginning it had a strong religious connection and exemplified the Christian insistence on compassion and care for the aged, the infirm, the needy, and the ill. In modern Britain the hospice movement developed gradually from its beginning in 1905, when the Sisters of Charity founded the St. James Hospice in London. The St. Christopher Hospice, also in London, founded in 1967, soon became known for its peaceful environment and expert medical and nursing care. The hospice movement has spread throughout Britain, North America, Australia, and Europe.

Mission hospitals. The spread of Western medicine and the founding of hospitals in the developing countries can be attributed in large part to the influence of the medical missionary. The establishment of mission hospitals gained momentum gradually in the second half of the 19th century. By the second half of the 20th century, however, this steady growth had already dwindled, since all but a few of the hospitals and dispensaries founded during that hundred years had been absorbed into the native health-care system. The Christian missionaries had a great influence on the creation of centres of Western medicine in many developing countries and in promulgating the concept of a hospital in which health care would be centralized and organized for the benefit of the ill and injured, many of whom would not otherwise have survived. The medical missionaries also promoted the idea and the ideals of nursing as a profession for native men and women.

Apart from its religious associations, a mission hospital functions as a general hospital in the sense that it admits all who need hospital care. A number of mission hospitals, however, have been devoted to specific diseases—for example, leprosy and diseases of the eyes. Perhaps the most important contribution made by mission hospitals is in the enormous numbers of persons, particularly women and children, who have been treated as outpatients.

Extended health care. With the advance in medical science and the ever-increasing cost of hospital operations, the progressive-care concept is more attractive, both for outpatient and inpatient care. Progressive care can be divided into five categories: (1) intensive care, (2) intermediate care, (3) self-care, (4) long-term care, and (5) organized home-care programs. Two of the categories, self-care and home-care programs, are relatively new departures from past practice and deserve special attention.

Categories of progressive care

Self-care facilities are organized into a separate unit in which ambulatory patients who require only diagnostic or convalescent care are given accommodations similar to those of a hotel. The patients are free to wear street clothes and to go to the hospital cafeteria. Such a ward or wing of a general hospital requires much less costly equipment than the intensive- or intermediate-care units and can be staffed with far fewer nurses and aides.

Home-care programs are for patients who need some care but not all of the treatment facilities of a hospital. The patients are provided with a range of individualized medical, nursing, social, and rehabilitative services in their own homes, coordinated through one central agency. Patients can be considered ready for home care when the following criteria are met: (1) diagnosis and a plan for treatment have been established; (2) inpatient hospital facilities are no longer required for proper care; (3) no more than two visits per week by physicians are required; (4) the nursing service has found that the physical environment of the home is such that the patient receives adequate care; (5) the patient is too ill to visit an outpatient clinic but does not need hospital care; (6) the family environment would have a therapeutic effect, and family members or others can be taught to provide the necessary care; and (7) the family and the patient prefer that care be provided at home. Even though home care conserves expensive acute-care beds, and although most patients on home care do as well as or better than expected, home-care programs have not been widely adopted.

Regional planning. Sweden and the former Soviet Union provide examples of advanced planning in the integration of hospital networks into coordinated health services. In both nations the government was charged with the responsibility of providing health care to all citizens. In Sweden financing is in part by compulsory health insurance.

Sweden is divided into health service regions; each region includes several counties and has a central hospital. Each county within a region has a county hospital with up to 1,000 beds and with specialized and outpatient facilities to serve a population of about 300,000. The counties, in turn, are divided into districts, each of which has a population of about 75,000 and is served by a district hospital, which usually has 300 or more beds. Smaller communities have health centres or ambulatory service centres that are not administered as part of the hospital system.

The Soviet Union took a somewhat different approach. In its thinly populated rural areas, general hospitals, called *uchastok* hospitals, served populations as small as 2,000 to 15,000 persons. These 15- to 100-bed general hospitals occupied the same premises and employed the same staff as general clinics (polyclinics) that provided general and specialized care. The hospital-clinic staff included a general physician, a surgeon, and a dental surgeon. Some larger *uchastok* centres also had a radiologist and a pathologist.

The next larger hospitals, the district hospitals, had 250–500 beds and usually had divisions for surgical, medical, obstetric, and pediatric services and provided care for in-

fectious diseases; some also included departments for eye, ear, nose, and throat disorders and for orthopedic surgery. Patients who could not be treated adequately in the district hospitals were referred to the next higher level, the regional hospital, which served a population of 1,000,000–5,000,000 people and contained up to 1,250 beds.

The republic hospital occupied the highest level in the Soviet system. Such a hospital, or complex of hospitals, served as a referral centre and had the responsibility of undergraduate medical education. Some were also associated with one or more research institutes.

Regional planning in North America is less advanced. One regional pattern is a satellite system, centred on a metropolis and applying the principle of progressive patient care. The system is focused on the efficient provision of comprehensive health care to the residents of the region. Less serious cases are handled in the outer, more accessible health facilities of the system; the more serious are referred to the inner hospitals of the ring or to the research and teaching hospital at the core.

Metropolitan planning council

The term metropolitan planning council is often used to denote an advisory planning group that coordinates services among member hospitals in a metropolitan area and decides such questions as where more beds are to be added. In North America, however, most hospitals are not government-operated, and it is difficult to achieve close cooperation among voluntary groups.

Public health services

Public health has been defined as the art and science of preventing disease, prolonging life, and promoting physical and mental health, sanitation, personal hygiene, control of infection, and organization of health services. From the normal human interactions involved in dealing with the many problems of social life, there has emerged a recognition of the importance of community action in the promotion of health and the prevention and treatment of disease; this is expressed in the concept of public health.

Comparable terms for public health medicine are social medicine and community medicine; the latter has been widely adopted in the United Kingdom, and the practitioners are called community physicians. The practice of public health draws heavily on medical science and philosophy and concentrates especially on manipulating and controlling the environment for the benefit of the public.

Concerns

It is concerned therefore with housing, water supplies, and food. Noxious agents can be introduced into these through farming, fertilizers, inadequate sewage disposal and drainage, construction, defective heating and ventilating systems, machinery, and toxic chemicals. Public health medicine is part of the greater enterprise of preserving and improving the public health. Community physicians cooperate with such diverse groups as architects, builders, sanitary and heating and ventilating engineers, factory and food inspectors, psychologists and sociologists, chemists, physicists, and toxicologists. Occupational medicine is concerned with the health, safety, and welfare of persons in the workplace. It may be viewed as a specialized part of public health medicine since its aim is to reduce the risks in the environment in which persons work.

The venture of preserving, maintaining, and actively promoting public health requires special methods of information-gathering (epidemiology) and corporate arrangements to act upon significant findings and put them into practice. Statistics collected by epidemiologists attempt to describe and explain the occurrence of disease in a population by correlating factors such as diet, environment, radiation, or cigarette smoking with the incidence and prevalence of disease. The government, through laws and regulations, creates agencies to oversee and formally inspect such things as water supplies, food processing, sewage treatment, drains, air contamination, and pollution. Governments also are concerned with the control of epidemic infections by means of enforced quarantine and isolation—for example, the health control that takes place at seaports and airports in an attempt to assure that infectious diseases are not brought into a country.

This section traces the historical development of public health, beginning in ancient times and emphasizing how various public health concepts have evolved. It outlines the organizational and administrative methods of handling these problems in the developed and the developing countries of the world. Special attention is given to the developing countries and to how the health problems, limitations of resources, education of health personnel, and other factors must be taken into account in designing health service systems. Finally, there are descriptions of the most recent developments in public health, together with some indications of the problems still to be solved.

HISTORY OF PUBLIC HEALTH

Beginnings in antiquity. Most of the world's primitive people have practiced cleanliness and personal hygiene, often for religious reasons, including, apparently, a wish to be pure in the eyes of their gods. The Old Testament, for example, has many adjurations and prohibitions about clean and unclean living. Religion, law, and custom were inextricably interwoven. For thousands of years primitive societies looked upon epidemics as divine judgments on the wickedness of mankind. The idea that pestilence is due to natural causes, such as climate and physical environment, however, gradually developed. This great advance in thought took place in Greece during the 5th and 4th centuries BC and represented the first attempt at a rational, scientific theory of disease causation. The association between malaria and swamps, for example, was established very early (503–403 BC), even though the reasons for the association were obscure. In the book *Airs, Waters, and Places,* thought to have been written by Hippocrates in the 5th or 4th century BC, the first systematic attempt was made to set forth a causal relationship between human diseases and the environment. Until the new sciences of bacteriology and immunology emerged well into the 19th century, this book provided a theoretical basis for the comprehension of endemic disease (that persisting in a particular locality) and epidemic disease (that affecting a number of people within a relatively short period).

Greek theories of disease causation

The Middle Ages. In terms of disease, the Middle Ages can be regarded as beginning with the plague of 542 and ending with the Black Death (bubonic plague) of 1348. Diseases in epidemic proportions included leprosy, bubonic plague, smallpox, tuberculosis, scabies, erysipelas, anthrax, trachoma, sweating sickness, and dancing mania (see INFECTIOUS DISEASES). The isolation of persons with communicable diseases first arose in response to the spread of leprosy. This disease became a serious problem in the Middle Ages and particularly in the 13th and 14th centuries.

The Black Death

The Black Death reached the shores of southern Europe from the Middle East in 1348 and in three years swept throughout Europe. The chief method of combating plague was to isolate known or suspected cases as well as persons who had been in contact with them. The period of isolation at first was about 14 days and gradually was increased to 40 days. Stirred by the Black Death, public officials created a system of sanitary control to combat contagious diseases, using observation stations, isolation hospitals, and disinfection procedures. Major efforts to improve sanitation included the development of pure water supplies, garbage and sewage disposal, and food inspection. These efforts were especially important in the cities, where people lived in crowded conditions in a rural manner with many animals around their homes.

During the Middle Ages a number of first steps in public health were made: attempts to cope with the unsanitary conditions of the cities and, by means of quarantine, to limit the spread of disease; the establishment of hospitals; and provision of medical care and social assistance.

The Renaissance. Centuries of technological advance culminated in the 16th and 17th centuries in a number of scientific accomplishments. Educated leaders of the time recognized that the political and economic strength of the state required that the population maintain good health. No national health policies were developed in England or on the Continent, however, because the government lacked the knowledge and administrative machinery to

carry out such policies. As a result, public health problems continued to be handled on a local community basis, as they had been in medieval times.

Scientific advances of the 16th and 17th centuries laid the foundations of anatomy and physiology. Observation and classification made possible the more precise recognition of diseases. The idea that microscopic organisms might cause communicable diseases had begun to take shape.

Among the early pioneers in public health medicine was John Graunt, who in 1662 published a book of statistics, which had been compiled by parish and municipal councils, that gave numbers for deaths and sometimes suggested their causes. Inevitably the numbers were inaccurate but a start was made in epidemiology.

National developments in the 18th and 19th centuries. Nineteenth-century movements to improve sanitation occurred simultaneously in several European countries and were built upon foundations laid in the period between 1750 and 1830. From about 1750 the population of Europe increased rapidly, and with this increase came a heightened awareness of the large numbers of infant deaths and of the unsavoury conditions in prisons and in mental institutions.

This period also witnessed the beginning and the rapid growth of hospitals. Hospitals founded in Britain, as the result of voluntary efforts by private citizens, helped to create a pattern that was to become familiar in public health services. First, a social evil is recognized and studies are undertaken through individual initiative. These efforts mold public opinion and attract governmental attention. Finally, such agitation leads to governmental action.

This era was also characterized by efforts to educate people in health matters. In 1852 Sir John Pringle published a book that discussed ventilation in barracks and the provision of latrines. Two years earlier he had written about jail fever (now thought to be typhus), and again he emphasized the same needs as well as personal hygiene. In 1754 James Lind published a treatise on scurvy, a disease caused by a lack of vitamin C.

The health of industrial workers

As the Industrial Revolution developed, the health and welfare of the workers deteriorated. In England, where the Industrial Revolution and its bad effects on health were first experienced, there arose in the 19th century a movement toward sanitary reform that finally led to the establishment of public health institutions. Between 1801 and 1841 the population of London doubled; that of Leeds nearly tripled. With such growth there also came rising death rates. Between 1831 and 1844 the death rate per thousand increased in Birmingham from 14.6 to 27.2; in Bristol, from 16.9 to 31; and in Liverpool, from 21 to 34.8. These figures were the result of an increase in the urban population that far exceeded available housing and of the subsequent development of conditions that led to widespread disease and poor health.

Around the beginning of the 19th century humanitarians and philanthropists in England worked to educate the population and the government on problems associated with population growth, poverty, and epidemics. Thomas Malthus wrote in 1798 about population growth, its dependence on food supply, and the control of breeding by contraceptive methods. The utilitarian philosopher Jeremy Bentham propounded the idea of the greatest good of the greatest number as a yardstick against which the morality of certain actions might be judged. Thomas Southwood Smith founded the Health of Towns Association in 1839, and by 1848 he served as a member of the new government department, then called the General Board of Health. He published reports on quarantine, cholera, yellow fever, and the benefits of sanitary improvements.

The Poor Law Commission, created in 1834, explored problems of community health and suggested means for solving them. Its report, in 1838, argued that "the expenditures necessary to the adoption and maintenance of measures of prevention would ultimately amount to less than the cost of the disease now constantly engendered." Sanitary surveys proved that a relationship exists between communicable disease and filth in the environment, and it was said that safeguarding public health is the province of the engineer rather than of the physician.

The Public Health Act of 1848 established a General Board of Health to furnish guidance and aid in sanitary matters to local authorities, whose earlier efforts had been impeded by lack of a central authority. The board had authority to establish local boards of health and to investigate sanitary conditions in particular districts. Since this time several public health acts have been passed to regulate sewage and refuse disposal, the housing of animals, the water supply, prevention and control of disease, registration and inspection of private nursing homes and hospitals, the notification of births, and the provision of maternity and child welfare services.

Advances in public health in England had a strong influence in the United States, where one of the basic problems, as in England, was the need to create effective administrative mechanisms for the supervision and regulation of community health. In America recurrent epidemics of yellow fever, cholera, smallpox, typhoid, and typhus made the need for effective public health administration a matter of urgency. The so-called Shattuck report, published in 1850 by the Massachusetts Sanitary Commission, reviewed the serious health problems and grossly unsatisfactory living conditions in Boston. Its recommendations included an outline for a sound public health organization based on a state health department and local boards of health in each town. In New York City (in 1866) such an organization was created for the first time in the United States.

Developments in Germany and France in the 19th century

Nineteenth-century developments in Germany and France pointed the way for future public health action. France was preeminent in the areas of political and social theory. As a result the public health movement in France was deeply influenced by a spirit of public reform. The French contributed significantly to the application of scientific methods for the identification, treatment, and control of communicable disease.

Although many public health trends in Germany resembled those of England and France, the absence of a centralized government until after the Franco-German War did cause significant differences. After the end of that war and the formation of the Second Reich, a centralized public health unit was formed. Another development was the emergence of hygiene as an experimental laboratory science. In 1865 the creation at Munich of the first chair in experimental hygiene signaled the entrance of science into the field of public health.

There were other advances. The use of statistical analysis in handling health problems emerged. The forerunner of the United States Public Health Service came into being, in 1878, with the establishment in the United States of port quarantine on a national basis and with assignment of enforcement of the quarantine to the Surgeon General of the Marine Hospital Service. (Port quarantine was the isolation of a ship at port for a limited period to allow time for the manifestation of disease.)

Developments from 1875. The work of an Italian bacteriologist, Agostino Bassi, with silkworm infections early in the 19th century prepared the way for the later demonstration that specific organisms cause a number of diseases. Some questions, however, were still unanswered. These included problems related to variations in transmissibility of organisms and in susceptibility of individuals to disease. Light was thrown on these questions by discoveries of human and animal carriers of infectious diseases.

19th-century developments in bacteriology

In the last decades of the 19th century the French chemist Louis Pasteur, the Germans Ferdinand Julius Cohn and Robert Koch, and others developed methods for isolating and characterizing bacteria; the English surgeon Joseph Lister developed concepts of antiseptic surgery; the English physician Ronald Ross identified the mosquito as the carrier of malaria; a French epidemiologist, Paul-Louis Simond, provided evidence that plague is primarily a disease of rats spread by rat fleas; and two Americans, Walter Reed and James Carroll, demonstrated that yellow fever is caused by a filterable virus carried by mosquitoes. Thus, modern public health and preventive medicine owe much to the early medical entomologists and bacteriologists. A further debt is owed bacteriology because of its offshoot, immunology.

In 1881 Pasteur established the principle of protective

vaccines and thus stimulated an interest in the mechanisms of immunity. The development of microbiology and immunology had immense consequences for community health. In the 19th century the efforts of health departments to control contagious disease consisted in attempts to improve environmental conditions. As bacteriologists identified the microorganisms that cause specific diseases, progress was made toward the rational control of specific infectious diseases.

In the United States the diagnostic bacteriologic laboratory was developed—a practical application of the theory of bacteriology, which evolved largely in Europe. These laboratories, established in many cities to protect and improve the health of the community, were a practical outgrowth of the study of microorganisms, just as the establishment of health departments was an outgrowth of an earlier movement toward sanitary reform. And just as the health department was the administrative mechanism for dealing with community health problems, the public health laboratory was the tool for the implementation of the public health program. Evidence of the effectiveness of this new phase of public health may be seen in statistics of immunization against diphtheria—in New York City the mortality rate due to diphtheria fell from 785 per 100,000 in 1894 to 1.1 per 100,000 in 1940.

While improvements in environmental sanitation during the first decade of the 20th century were valuable in dealing with some problems, they were of only limited usefulness in solving the many health problems found among the poor. In the slums of England and the United States malnutrition, venereal disease, alcoholism, and other diseases were widespread. Nineteenth-century economic liberalism held that increased production of goods would eventually bring an end to scarcity, poverty, and suffering. By the turn of the century, it seemed clear that deliberate and positive intervention by reform-minded groups, including the state, also would be necessary. For this reason many physicians, clergymen, social workers, public-spirited citizens, and government officials promoted social action. Organized efforts were undertaken to prevent tuberculosis, lessen occupational hazards, and improve children's health.

Poverty and disease

The first half of the 20th century saw further advances in community health care, particularly in the welfare of mothers and children and the health of schoolchildren, the emergence of the public health nurse, and the development of voluntary health agencies, health education programs, and occupational health programs.

In the second half of the 19th century two significant attempts were made to provide medical care for large populations. One was by Russia, and took the form of a system of medical services in rural districts; after the Communist Revolution, this was expanded to include complete government-supported medical and public health services for everyone. Similar programs have since been adopted by a number of European and Asian countries. The other attempt was prepayment for medical care, a form of social insurance first adopted toward the close of the 19th century in Germany, where prepayment for medical care had long been familiar. A number of other European countries adopted similar insurance programs.

In the United Kingdom, a royal-commission examination of the Poor Law in 1909 led to a proposal for a unified state medical service. This service was the forerunner of the 1946 National Health Service Act, which represented an attempt by a modern industrialized country to provide services to all people.

In recent years prenatal care has made a substantial contribution to preventive medicine, for it is hoped that through the education of mothers the physical and psychological health of families may be influenced and passed on to succeeding generations. Prenatal care provides the opportunity to educate the mother in personal hygiene, diet, exercise, the damaging effects of smoking, the careful use of alcohol, and the dangers of drug abuse.

Public health interests also have turned to such disorders as cancer, cardiac disease, thrombosis, lung disease, and arthritis, among others. There is increasing evidence that several of these disorders are caused by factors in the environment; for example, the association of cigarette smoking with certain lung and cardiovascular diseases. Theoretically, they are preventable if the environment can be altered. Health education is of great importance and is a responsibility of national and local government agencies as well as voluntary bodies. Life expectancy has increased in almost every country, except where public health standards are low.

MODERN ORGANIZATIONAL AND ADMINISTRATIVE PATTERNS

International organizations. Since ancient times, the spread of epidemic disease demonstrated the need for international cooperation for health protection. Early efforts toward international control of disease appeared in national quarantines in Europe and the Middle East. The first formal international health conference, held in Paris in 1851, was followed by a series of similar conferences aimed at drafting international quarantine regulations. A permanent international health organization was established in Paris in 1907 to receive notification of serious communicable diseases from participating nations, to transmit this information to the member nations, and to study and develop sanitary conventions and quarantine regulations on shipping and train travel. This organization was ultimately absorbed by the World Health Organization (WHO) in 1948.

In the Americas, the organization of international health probably began with a regional health conference in Rio de Janeiro in 1887. From 1889 onward there were several conferences of American countries, which led ultimately to the establishment of the Pan-American Sanitary Bureau; this was made a regional office of WHO in 1949, when it became known as the Pan-American Health Organization.

The rise and decline of health organizations has been influenced by wars and their aftermaths. After World War I, a Health Section of the League of Nations was established and functioned until World War II. After the war, the United Nations Relief and Rehabilitation Administration (UNRRA) was set up; it processed displaced persons in such a way as to prevent the spread of disease. It was responsible for the planning steps that led to the establishment in 1948 of the World Health Organization as a special agency of the United Nations. WHO is concerned with physical, mental, and social well-being and not merely with the absence of disease.

Establishment of WHO

The work of WHO is carried out under the direction of the World Health Assembly, which has representatives from the member states. The first assembly gave consideration to diseases and problems that exist in large areas of the world and that lend themselves to international action. Malaria, tuberculosis, venereal disease, the promotion of health, environmental conditions responsible for a significant proportion of deaths, and nutrition were given priority. Other areas of need have been included since.

Among important functions of the organization are the advisory services offered to governments through its regional staff. Regional offices in a number of countries, both industrialized and developing, as well as local representatives in many developing countries, help WHO maintain contact with needs and sources of financial aid. In specialized fields, a number of expert committees consider specific questions.

WHO maintains close relationships with other United Nations agencies, particularly the United Nations Children's Fund (UNICEF) and the Food and Agriculture Organization (FAO), and with international labour organizations. From its inception in 1946, UNICEF focused its aid on maternal and child health services and the control of infections, especially in children. Priority has been given to the production of vaccines, the institution of environmental sanitation, the provision of clean water, and the training of local personnel in their own countries (especially in rural areas). Aid is channeled through organized health services in developing countries. Recent efforts have concentrated on persuading governments to undertake national surveys to identify the basic needs of their children and to devise appropriate national policies.

The work of WHO includes three main categories of

activities. First, it is a clearinghouse for information about disease throughout the world, and it has developed a uniform system for reporting diseases and causes of death. It has established internationally accepted standards for drugs and drawn up a list of "essential" (effective, cheap, and reliable) drugs. It has sponsored and financed many research projects throughout the world. Second, WHO has promoted mass campaigns to control epidemic and endemic diseases, a substantial number of which have been quite successful. Third, WHO attempts to strengthen and expand the public health administration and services of member nations by providing technical advice, teams of experts to carry out surveys and demonstrate projects, and aid in support of regional and national health development projects.

Departments of health

Developed nations. Methods of health administration vary from country to country. Major health functions are frequently grouped in a department that is responsible for health and for related functions. In the United Kingdom they are carried out by the Department of Health and Social Security; in the United States the Department of Health and Human Services controls the programs covered by national legislation.

Few central departments of health are all-embracing; other departments also operate medical programs of some sort. No country places the health services of its military forces under the central health agency. Because unity of control at the centre is impracticable, coordination is important. Central administration is further complicated in federal systems. In the United States there are 50 states, no two of which have the same patterns of health organization.

Patterns shared. The official responsible for the administration of national health affairs is in most cases a member of the Cabinet. Advisory councils are frequently used to bring the ideas of leading scientists, health experts, and community leaders to bear on major national health problems.

An organization that provides basic community health services under the direction of a medical officer is called a local health unit. It is usually governed by a local authority. Its programs may include maternal and child health, communicable-disease control, environmental sanitation, maintenance of records for statistical purposes, health education of the public, public health nursing, medical care, and, often, school health services. The local health unit can provide the administrative framework for a wider range of community health services, including the care of the aged, of the physically handicapped, and of the chronically ill and mental health services. Although social welfare services may be provided by a separate agency, there are advantages in amalgamating health and welfare services, because a family's health and social problems tend to be interrelated. In England welfare and public health are often integrated at the local level, whereas in the United States they are almost always separate.

The population served by a local health unit may be only a few thousand or several hundred thousand. There are substantially different problems involved in administering health services for a large rural area that is sparsely populated and a municipality with a population of one or two million.

One problem of administering local health services is the question of whether they should be run by independent local authorities or organized regionally to ensure coordination and effective referral and to avoid duplication of services.

Types of public medical service

Medical care is provided as a public service to some degree in most countries. It may be limited to the hospitalization of persons afflicted with certain ailments—for example, mental disease, tuberculosis, chronic illness, and acute infections. Comprehensive health services may be provided for some specific population groups, as in Canada and the United States, where the federal government provides care for Indians and Eskimos. Many countries have compulsory medical insurance, and some combine the socialization of hospitals with medical insurance covering general medical care, as in Denmark. Full-scale socialization of health services exists in a few countries, including the United Kingdom and New Zealand.

In countries such as The Netherlands and the United States, where voluntary and nonprofit organizations support a considerable share of the health services and operate most of the general hospitals, there is pluralism in health administration. This makes coordination difficult, but voluntary effort has the advantages of involving citizens directly in the development of health services and of promoting experimentation in administration.

Levels of health care

There is a trend toward regional planning of comprehensive health services for defined populations. In an idealized plan, the first level of contact between the population and the system, which can be called primary care, is provided by health personnel who work in community health centres and who reach beyond the health centres into the communities and homes with preventive, promotive, and educational services. At the next level of care, specialists in community hospitals provide secondary care for patients referred from the primary-care centres. Finally, tertiary, or superspecialty, care is provided by a major medical centre. The various levels of this regional scheme are linked by a two-way flow of medical records, patients, and health personnel. Regionalization has been most fully achieved in Europe and least so in North America, where voluntary hospitals provide most of the short-term general services and retain autonomy in their administration.

Variations. Among the developed nations, there is substantial variation in the organization and administration of health services. The United Kingdom, for example, has a National Health Service with substantial autonomy given to local government for implementation. The United States has a pluralistic approach to health services, in which local, state, and national governments have varying areas of responsibility, with the private sector playing a prominent role.

During the first half of the 20th century in Britain, the emphasis shifted gradually from environmental toward personal public health. A succession of statutes, of which the Maternity and Child Welfare Act (1918) was probably the most important, placed responsibility for most of the work on county governments. National health insurance (1911) gave benefits to 16,000,000 workers and marked the beginning of a process upon which the National Health Service Act (1946) was built.

The National Health Service Act provided comprehensive coverage for most of the health services, including hospitals, general practice, and public health. The service remained at the periphery, however, in three types of care: (1) Primary medical care is given by family physicians or general practitioners. This service is organized locally by an executive council. Each general practitioner is responsible for providing primary care to a group of people on a particular registry. (2) Specialist consultation and outpatient and inpatient treatment are provided in hospitals under the direction of regional authorities. A later concept makes each district general hospital responsible for providing hospital services for a defined population. (3) Services, such as health visiting, home nursing, home helps, domiciliary midwifery, the prevention of illness, and the provision of health centres are the responsibility of local authorities.

In the former Soviet Union the protection and promotion of public health was the responsibility of the state. There was free public access to all forms of medical care. The principles of the health services were complete integration of curative and preventive services, medicine as a social service, preventive programs, health centres or polyclinics (clinics in which a variety of diseases were handled), and community participation.

The public health services for the Soviet Union were directed by the Ministry of Health. Each of 15 republics of the union had its own ministry. Each republic was divided into *oblasti* (provinces), which in turn were divided into *rayony* (municipalities) and finally into *uchastoki* (districts). Each subdivision had its own health department accountable to the next highest division (see above *The practice of public health*).

There were well-established referral procedures, from the polyclinics and smaller hospitals in the *uchastoki* to the

larger *rayon* hospitals, and from feldshers (paramedical personnel trained in medical care) and other paramedical personnel to internists and pediatricians and, when necessary, to more highly specialized personnel.

The health services of the United States can be considered at three levels: local, state, and federal.

Levels of service

Locally in cities or counties, there is substantial autonomy within broad guidelines developed by the state. The size and scope of local programs vary, but some of their functions are control of communicable diseases; clinics for mothers and children, particularly for certain preventive and diagnostic services; public health nursing services; environmental health services; health education; vital statistics; community health centres, hospitals, and other medical care facilities; community health planning and coordination.

At the state level, a department of health is charged with overall responsibility for health, though a number of agencies may actually be involved. The state department of health usually has five functions: public health and preventive programs; medical and custodial care such as the operation of hospitals for mental illness; expansion and improvement of hospitals, medical facilities, and health centres; licensure for health purposes of individuals, agencies, and enterprises serving the public; and financial and technical assistance to local governments for conducting health programs.

At the federal, or national, level, the Public Health Service of the Department of Health and Human Services is the principal health agency, but several other departments have health interests and responsibilities. Federal health agencies accept responsibility for improving state and local services, for controlling interstate health hazards, and for working with other countries on international health matters. The federal government also has the following specific responsibilities: (1) protecting the United States from communicable diseases from abroad; (2) providing for the medical needs of military personnel, veterans, merchant seamen, and American Indians; (3) protecting consumers against impure or misbranded foods, drugs, and cosmetics; and (4) regulating production of biological products, such as vaccines. In addition, the federal government promotes and supports medical research, health services, and educational programs throughout the country.

Voluntary effort is a significant part of health work in the United States. There are more than 100,000 voluntary agencies in the health field functioning mostly at the local level but also at state and national levels. Supported largely through private sources, these agencies contribute to programs related to education, research, and health services.

Channels for medical care

Medical care is provided and paid for through many channels, including public institutions, such as municipal, county, state, and federal health centres, hospitals, and medical care programs, and through private hospitals and private practitioners working either alone or, increasingly, in groups. Generally, medical care is financed by public funds, voluntary health insurance, or personal payment. There is a trend away from the traditional fee-for-service payment to individual practitioners toward prepaid-care systems including health teams working at community, health centre, and hospital levels.

Thus, in the United States there is great variety in the content, scope, and quality of health services. These services are provided by several independent agencies. In effect, however, they constitute a working partnership for the protection and promotion of human health.

Recently, two factors have contributed to rapid change in the orientation of health services in the United States. One of these is an increasing awareness that, while the existing system of health services provides high quality care for many, there are others for whom the care is either lacking or unsatisfactory. The second factor is that of steeply rising costs of medical care. These two issues have led to reconsideration of the entire system of personal medical care and proposals for new systems of providing and financing health care.

Developing nations. *Patterns shared.* Developing countries have sometimes been influenced in their approaches to health care problems by the developed countries that have had a role in their history. The countries in Africa and Asia that were once colonies of Britain have educational programs and health-care systems that reflect British patterns, though there have been adaptations to local needs. Similar effects may be observed in countries influenced by France, The Netherlands, and Belgium.

Despite variations from country to country, a common, if somewhat idealized, administrative pattern may be drawn for developing countries. All health services, except for a small amount of private practice, are under a ministry of health, in which there are about five bureaus, or departments—hospital services, health services, education and training, personnel, and research and planning. Hospital and health services are distributed throughout the country. At the periphery of the system are dispensaries, or health outposts, often manned by one or two persons with limited training. The dispensaries are often of limited effectiveness and are upgraded to full health centres when possible. Health centres and their activities are the foundation of the system. Health centres are usually staffed by auxiliaries who have four to 10 years of basic education plus one to four years of technical training. The staff may include a midwife, an auxiliary nurse, a sanitarian, and a medical assistant. The assistants, trained in the diagnosis and treatment of sickness, refer to a physician the problems that are beyond their own competence. Together, these auxiliaries provide comprehensive care for a population of 10,000 to 25,000. Several health centres together with a district hospital serve a district of about 100,000 to 200,000 people. All health services are under the responsibility of the district medical officer, who, assisted by other professional and auxiliary personnel, integrates the health efforts into a comprehensive program.

The typical administrative pattern

Of central importance is the distribution of responsibilities between auxiliaries and professionals. The auxiliaries, by handling the large number of relatively simple problems, allow the professionals to look after only the more complex problems, to supervise and teach the auxiliaries, and to plan and manage the programs.

The district hospital is dependent on a regional hospital, to which patients with complex problems can be referred for more specialized services. Administrative direction of both regional health services and regional hospital services can be combined at this level under a regional medical officer. The central administration of the ministry of health provides policies and guidance for an entire health service and, in some instances, also provides a central planning unit.

Problems of transportation and communication over great distances, shortages of staff and other resources, and inadequacies in staff preparation and motivation often lead to malfunctions in the system. Nonetheless, the public health services developed in African and Asian countries have generally provided a sound basis for future development within the framework of national development.

Variations. The organization of public health services in Latin-American countries differs substantially from those of Africa and Asia; these differences are an expression of their different historical backgrounds. The Latin-American countries are generally more affluent than those of Asia and Africa. Private practice is more widespread, and private or voluntary agencies are more prominent. Health services are provided largely by local and national governments. Many Latin-American countries also have systems of clinics and hospitals for workers financed by employers and workers. The distribution of health services, with health centres, hospitals, and preventive services, is roughly similar to Africa and Asia. The Latin-American countries, however, have used auxiliaries less than African and Asian countries. Latin America has pioneered in the development of health-planning methods. Chile has one of the most advanced approaches to health planning in the world.

Differences between Latin America and Africa

Thailand was never colonized and therefore has no historical influence favouring any particular pattern of health services. The Thai Ministry of Health has a well-developed system of hospitals and health centres across the country to serve both rural and urban people. It differs from the pattern described in the previous section in that, despite

the extreme shortages of physicians and nurses in rural areas, the nation has been reluctant to use auxiliaries for medical care. It does, however, use auxiliary midwives and sanitarians. Hospital services and public health services have separate administration. Within the public health services, there are a number of separate divisions—*e.g.*, for tuberculosis, sexually transmitted diseases, and nutrition—each with its own staff, budget, and facilities. The trend elsewhere has been away from relatively independent, disease-oriented approaches and toward integrated systems in which the same network of health services handles most problems.

Health problems and obstacles. The difficulties of providing health services for the people of the developing nations involve a cluster of interrelated problems. These arise from the nature of the diseases and hazards to health, insufficient and maldistributed resources, the design of health service systems, and the education of health personnel in those systems. Woven through the health programs of the developing nations and complicating them at both family and national levels are the pressures associated with rapidly growing populations.

There are differences not only in the kinds of diseases of different countries but also in the rates at which they occur and in the age groups involved. Life expectancy in some countries is less than half that in others, principally because of high death rates among small children in the developing countries. In much of Southeast Asia, for example, 40 percent of children die by their fourth year, a death rate not reached until age 60 in North America. The infant (under one year of age) mortality rate in Central and South America is two to four times that in North America, and the death rate in children one to four years of age is as much as 25 times greater. The differences for Central Africa are even more striking: infant mortality in some areas has been 12 times that in the United States, and the mortality in preschool children has been more than 60 times the U.S. figure.

Infant mortality rates

The principal causes of sickness and death among small children in the developing world are diarrhea, respiratory infections, and malnutrition, all of which are intimately related to culture, custom, and economic status. Malnutrition may result from food customs when taboos and simple oversight lead to deprivation of children. Gastroenteritis (inflammation of the lining of the stomach and intestines, usually with accompanying diarrhea) and respiratory infections are often due to infectious organisms that are not susceptible to antibiotics. The interrelationships of these diseases increase the complexity of treating them. Malnutrition is often the underlying culprit; not only does it cause damage itself, such as retardation of physical and mental development, but it also seems to set the stage for other illnesses. A malnourished child develops gastroenteritis, inability to eat, further weakness, and then dehydration. The weakened child is susceptible to a lethal infection, such as pneumonia. Or, to complete the vicious circle, infection can affect protein metabolism in ways that contribute to malnutrition.

Another factor that contributes to this is family size. Malnutrition, with associated death and disability, occurs most often in children born into large and poorly spaced families. The resulting high death rate among small children often reinforces the tendency of parents to have more children. People are not inclined to limit the size of their families until it is apparent that their children have a reasonable chance of survival. Thus, there is a fertility–mortality cycle in which high fertility, reflected in large numbers of small children crowded into a poor home, leads to high childhood mortality, which, in turn, encourages high fertility. This is the basis of the belief that population-control programs should include effective means of reducing unnecessary deaths among children.

Ratios of medical personnel to population

Among limitations of resources, shortages of trained personnel are among the most important; ratios of population to physicians, nurses, and beds provide an indication of the seriousness of these deficiencies and also of the great differences from country to country. Thus, the proportion of population to physicians in developing countries varies drastically.

Money is a crucial factor in health care—it determines how many health personnel can be trained, how many can be maintained in the field, and the resources that they will have to work with when they are there. Governmental expenditures on health care vary greatly from country to country.

As it attempts to provide health care for its people, a nation, on the one hand, must meet the urgent and complex problems, such as obstetric and surgical emergencies for which hospital care is essential. On the other hand, it must reach into the communities and homes to find those who need care but do not seek it and must discover the causes of such diseases as malnutrition and gastroenteritis.

Education of health personnel. In the education of health personnel, a particular set of problems emerges. Educational programs for auxiliaries are suited to the local situation, perhaps because they were not established in the more developed nations. Medical and nursing education, on the other hand, is similar to that of the more advanced countries, and it prepares students better for working in industrialized nations than in their own. This misfit between education and the jobs to be done has probably contributed substantially both to the ineffectiveness of health service systems and to the migration of professional personnel to the more developed countries.

PROGRESS IN PUBLIC HEALTH

Developed nations. Among the more developed nations the following trends are apparent.

Increasing interest of national governments. Formerly, governments were chiefly concerned with basic health problems, such as environmental sanitation, medical care of the poor, quarantine, and the control of communicable diseases. Gradually, they have extended their activities into the field of medical care services in the home, clinic, and hospital, so as to provide comprehensive health care for entire communities. Three factors have influenced this trend: (1) the nongovernmental voluntary agencies have been unable to meet the rising cost of medical care; (2) there is an increasing appreciation of the economic loss to a country from sickness; and (3) there is an increasing public interest in social services. Health and social welfare are now recognized as complementary, and social legislation tends to cover both areas. There is an administrative trend toward a close cooperation between health and social welfare services.

Factors in the increase of government involvement

Changing concepts of preventable disease. Until recently, the term preventable disease referred to a circumscribed group of infectious diseases. The term has acquired a broader meaning, however, as epidemiological methods are applied to other conditions. Preventive health services now deal with a wide range of health hazards, such as malignant tumours, rheumatism, cardiovascular diseases, other chronic and degenerative diseases, and even accidents.

Integration of preventive and medical care services. Medical care had its origin in the humanitarian motive of caring for the sick, while preventive health services sprang from the need to protect a healthy environment from epidemic diseases. They grew apart, but recently the trend has been to integrate them within a comprehensive health service. Such an integration was the fundamental principle of public health in the U.S.S.R., in which all local health services were centred in the district hospital under one administration. In European countries, especially in rural areas, the two branches are brought together by the local medical practitioner. The focal point of many discussions on medical care is the role that the hospital should play in health services. Many feel that its influence at present is too restricted and that it should spread beyond its walls to health centres and homes.

Comprehensive health service

Provisions directed toward better mental health. Mental health now has a place in the preventive services. Improvements in arrangements for mental health include the provision of outpatient clinics and inpatient accommodations at general hospitals for early mental cases, an increase in child-guidance and marriage-guidance clinics, and schemes for the care of alcoholics and drug addicts. There have also been significant developments in the treat-

ment of maladjusted members of society. Gains in understanding of psychoneuroses by general practitioners and the development of research facilities are also noteworthy.

Growing emphasis on health education. Many countries have expanded their commitment to health education, usually in cooperation with voluntary agencies. The most effective work is carried out at the local level, especially in schools. The trend is toward an expansion of health education as an essential preventive health service.

The biostatistical, epidemiological approach. A statistical service is essential in planning, administering, and evaluating health services. The interest of public authorities in medical-care schemes has increased the importance of statistics on the incidence of diseases and other problems, as well as the epidemiology necessary to combat them. Both are vital in the planning, organization, and evaluation of medical-care schemes. Traditionally, the epidemiological method was used for infectious diseases, but it is now being used increasingly for noninfectious diseases and the problems of medical care.

Changes resulting from an aging population. In more affluent nations, an increase in older age groups brings about the need for public health facilities to provide special services for them. Health care of the elderly includes measures to prevent premature aging and the chronic and degenerative diseases and to confront the psychological problems resulting from loneliness and inactivity. Geriatric clinics have been set up to meet these needs and to conduct research into the process of senescence.

Concern regarding the quality of the environment. There is widespread concern about environmental deterioration. Controlled atomic radiation has created new hazards to health, such as the potential pollution of air or water by radioactive discharges, the possible effects from radioactive fallout on the public generally, and the dangers to workers in atomic installations in industry. A growing population requires an increase in industrial and commercial activities, which add to the volume of pollutants that threaten the atmosphere, rivers, lakes, and oceans and have destructive effects on natural ecology. Individual countries have taken steps toward the control of environmental deterioration, and means of international regulation have also been proposed.

New hazards to health

Developing nations. In view of the large numbers of serious health problems in the developing nations and their limited resources for dealing with them, it is understandable that along with substantial progress there would be some stagnation, or even regression.

Communicable-disease control. Smallpox and malaria are examples of diseases that have been brought under closer control throughout the world. For other diseases, such as hepatitis (liver inflammation), rabies, leprosy, and sleeping sickness, there have been important growths in understanding that may contribute to their eventual control.

Disease problems that await solution. El Tor cholera, which has appeared in epidemic form in previously uninvolved areas, represents one of the most serious challenges to public health. Venereal disease, an old problem, has increased in incidence. Certain parasitic diseases have spread as humans have brought about changes in their environment—the increase in schistosomiasis (infestation with blood fluke by means of snails as the intermediate hosts) in irrigation and man-made lake areas is an example. Widespread malnutrition, particularly protein–calorie malnutrition in small children, remains a problem. Protein-rich food supplements and more effective educational programs are being developed to combat it.

Population growth

Family health. The problems of rapidly growing populations have important consequences at both the family and the national level. Problems of maternal and child health, human reproduction, and human genetics, including family planning, are now seen as aspects of the greater problem of the health of the whole family as a single and fundamental social unit. Accordingly, family health is a matter deserving high priority among the public health services.

Health manpower. There is widespread recognition of inadequacies in both number and education of health personnel. The trend is toward coordinating the education of health personnel with the particular health service in which they will function. This trend requires close relationships between educational institutions and the agencies responsible for health services.

Comprehensive community health services. The fragmentation of earlier health service organizations, such as programs concerned with only a single disease and the separation of curative and preventive services, is giving way to more comprehensive organizational patterns. Health promotion, disease prevention, and the curing and rehabilitation of the ill are brought together into one network of integrated services that reaches to the community level.

National health planning. Complex decision making is involved in allocating limited health service resources to large numbers of people. As a result, there has been an increasing emphasis on the health-planning process and on the design of more effective health-service systems. A number of countries have established health-planning units in the ministry of health or the national planning organization. An important aspect of national health planning is the close coordination between planning, budgeting, implementing, and evaluating programs.

Clinics

A clinic is an organized medical service offering diagnostic, therapeutic, or preventive treatment to ambulatory patients. Often in Europe and occasionally in the United States the term covers the entire teaching centre, including the hospital and the ambulatory-patient facilities. The medical care offered by a clinic may or may not be connected with a hospital.

The term clinic may be used to designate all the activities of a general clinic or only a particular division of the work; *e.g.*, the psychiatric clinic, neurology clinic, or surgery clinic. The entire activity when connected with a hospital is called the outpatient department, and the specific subdivisions are referred to as clinics.

The London Dispensary

The first clinic in the English-speaking world, the London Dispensary, was founded in 1696 as a central means of dispensing medicines to the sick poor whom the physicians were treating in the patients' homes. The New York City, Philadelphia, and Boston dispensaries, founded in 1771, 1786, and 1796, respectively, had the same objective. Later, for the sake of convenience, physicians began to treat their free patients at the dispensary. The number of such clinics did not increase rapidly, and as late as 1890 only 132 were operating in the United States. The impetus for the mushroomlike growth that has occurred since that time came with the rapid growth of hospitals and also from the public health movement.

HOSPITAL CLINICS

During the late 1800s the modern concept of a hospital began to take shape. During this period some of the hospitals connected with medical schools inaugurated outpatient departments for the purposes of teaching and charity. The advantages of providing ambulatory care close to the facilities of a hospital became apparent, and such hospital clinics multiplied rapidly.

The organization of a hospital clinic in general follows that of the inpatient facilities. Hospital clinics are primarily concerned with acute diseases, and the physicians in the clinics are usually the same physicians who treat inpatients in the hospital.

In many hospital clinics, especially those in countries that do not have national health insurance programs, care is made available only to the medically indigent, and no professional fee is charged. Practically all such clinics, however, charge a small registration fee if the patient is financially able to pay; income from such fees helps pay operating costs. A number of successful attempts have been made to extend hospital clinic care to paying patients. Most of this effort has been in the area of lower income groups although in a few hospitals no limit is placed on income in determining eligibility for care. The hospitals of the University of Chicago, for example, began operating a clinic on such a basis in 1928.

PUBLIC HEALTH CLINICS

The public health movement has been mainly concerned with preventive medicine, child and maternal health, and other medical problems affecting broad segments of the population. The first public health clinics were established in the late 19th century. In 1890 A. Pinard set up a maternal dispensary or antenatal clinic at the Maternité Baudelocque in Paris. Milk distribution centres were set up in France by J. Comby (1890) and in Britain by F.D. Harris (1899). Infant welfare clinics were established in Barcelona (1890); and clinics for older children were founded in St. Pancras, London, by J.F.J. Sykes (1907).

The first clinics

Unlike hospital clinics, which have had their greatest growth in the cities, public health clinics are located chiefly in smaller towns and villages. In the United States the first great movement in creating public health clinics resulted in the founding of the National Association for the Study and Prevention of Tuberculosis in 1904. It was the association's goal to study and prevent tuberculosis by making clinic facilities available for free examination and treatment in every city and county. Other nationwide, private health agencies in specialized medical fields quickly adopted this method to improve the quality and extend the quantity of medical service in their fields. Local governmental health units operate similar clinics for the prevention of communicable disease and long-term illness. Such clinics are generally concerned with one particular medical interest, usually one of the following: tuberculosis, sexually transmitted diseases, prenatal care, well-baby care, teeth, tonsils, eyes, crippled children, and mental health.

Traveling clinics

There is a tendency toward the establishment of traveling clinics, such as dental clinics for schoolchildren. Often no charge is made for service in public health clinics, and for many medical conditions no income restrictions are imposed. A few are operated in connection with hospitals, but most such clinics use public buildings or space furnished by welfare and other social agencies. Financial support is received mostly from the same sources.

PRIVATE CLINICS

The advantages of group medical service, with facilities and technical personnel beyond the means of an individual practitioner plus the benefit of group consultation, have encouraged the establishment of pay or private clinics. Such a clinic is essentially a voluntary association of physicians engaged in the practice of medicine on an organized group basis. Common administration and facilities are used, and the resulting expense and income are shared according to a predetermined plan. To be classified as a group clinic the relationship between each physician and the organization must be defined in a legal agreement. The relationship usually takes the form of a partnership. Several of these, such as the Mayo Clinic, in Rochester, Minn., have achieved a national reputation and attract patients from a wide area. Most of these organized group clinics are general clinics—*i.e.*, they have several of the different medical specialties represented on their staffs. A number of private clinics, however, limit their work to one medical specialty. An enterprise of special interest is the London Clinic, established in 1936 by a group of prominent consultant surgeons and physicians who wished to make available to their private patients a place where the comforts and privacy of a nursing home could be combined with facilities for diagnosis and therapy such as exist only in the larger general hospitals.

Usually the group is organized independently of any hospital or other agency, but in some instances such clinics own and operate their own hospital facilities. In other instances the clinic is a part of a prepaid health service plan. This latter pattern has received impetus in recent years as labour unions have set up medical clinics supported by welfare benefits contributed by employers. The United Mine Workers, for example, has established a system of such clinics in hospitals constructed by the union in the coal-mining areas of Virginia and West Virginia.

HEALTH CENTRES

In 1910 the first health centres, or multiple clinics, were established in Pittsburgh and Wilkes-Barre, Pa. Others were opened in 1913 in New York City and in 1916 in Boston and Philadelphia. In 1920 in Britain a consultative council on medical and allied services (Dawson Committee) described a health centre as an institution wherein various medical services, preventive and curative, are brought together. Under Section 21 of the National Health Service Act, 1946, local health authorities provide, equip, maintain, and staff health centres to offer facilities for all or any of the following services: general medical and dental, pharmaceutical, hospital outpatient and health education, and care of expectant and nursing mothers. The prenatal and postnatal clinics include periodic medical and dental examinations, classes in parenthood and relaxation, and welfare foods. Activities in child welfare clinics comprise education in all aspects of motherhood, periodic medical and dental examinations, advice on mental health problems, immunization and vaccination, and distribution of welfare foods.

Services

POLYCLINICS

In the U.S.S.R. the polyclinic (*poliklinika*) was created in order to combine the function of a hospital outpatient department with that of a general-practitioner health centre. Factory workers and their families could attend general polyclinics attached to major factories, and many special children's polyclinics were built in the towns. A typical urban polyclinic, which was usually associated with a hospital, included reception and waiting rooms, registration desk, and consulting and treatment rooms of the following: internist, pediatrician, gynecologist, surgeon, eye specialist, ear, nose, and throat specialist, neurologist, urologist, and dentist. Rooms were often set aside for first aid, reception of infectious cases, and women and children's welfare, as well as a dental department, drugstore, pathological laboratory, X-ray department, gymnasium, and lecture hall. There were always fairly elaborate physiotherapy departments and usually large and small operating theatres.

FAMILY PLANNING CLINICS

The main purposes of the family planning service are to encourage parents to make responsible decisions about pregnancy that take into account the best interests of the family; to provide guidance to couples who wish to limit the size of their families; and to advise on the technical methods that are available for doing so. There are marked differences in attitude toward the desirability of a reduction in family size as between developed and developing countries. This difference is dominated by high infant and child mortality in most developing countries as compared with developed countries. (Ha.Sc.)

RELATED FIELDS

Nursing

The need for nursing is universal. The International Council of Nurses states that the function of nursing is fourfold—to promote health, prevent illness, restore health, and alleviate suffering—and that inherent in nursing is "the respect for life, dignity and the rights of man. It is unrestricted by considerations of nationality, race, creed, colour, age, sex, politics or social status. Nurses render health services to individuals, the family and the community and co-ordinate their services with those of related groups." Nurses form the largest group of health service workers throughout the world. As medical science advances, the health needs of a given population change and expectations for care rise, so that the potential for nursing service increases. The World Health Organization (WHO) stated in 1986 that "nursing and midwifery personnel have an even greater potential contribution to make to health

for all than they are already making. Nurses' potential lies in their role as providers of primary health care services in community settings, clinics, schools and industries as well as in hospitals."

HISTORY OF NURSING

When Christianity developed, with its teachings of duty, love, and brotherhood, caring for the sick gained new impetus. Among the early converts to Christianity were highborn Roman matrons. Phoebe, a friend of St. Paul, "succored many"; Marcella made her palace into a monastery for women; Fabiola turned her home into a hospital. These women and others like them exemplified new intellectual freedom for women and their participation in religious and social action at a high level.

For several centuries thereafter the spread of health work moved slowly. Monastic orders grew, and from them some health services radiated; but large areas of the world were untouched, and the monastic undertaking of health work seemed to diminish. Later, military and chivalric orders were founded, supporting the Crusades and combining the making of war with charitable and hospital work. Some established companion orders for women. Monastic and chivalric orders established in various forms among health workers the beginnings of hierarchical organization, amateur participation that provided the roots of volunteerism, and a sense of calling or vocation.

Nursing can be seen to rise from two wellsprings, one scientific, the other religious and social. Acceleration of scientific advancement in health began with the 16th century. During the 19th century the "germ theory" of disease was developed; ways of treating and preventing infectious diseases, then the largest cause of death, were introduced. Anesthesia was also discovered. It is often said that research produced more medical and health knowledge in the decades after World War II than in all previous centuries combined. The growing mass of new knowledge to be applied in health services by health workers challenged the educational system for physicians, nurses, and others and strained the system of distribution of services to an awakened public.

Paralleling these scientific advances were those made through the years in social and religious action. The work of St. Vincent de Paul and, later, of John Howard typify this kind of action. After making thorough studies of conditions, they recommended marked changes in hospitals and prisons. A new dimension, planning based on facts, thus was added. St. Vincent, with St. Louise de Marillac, founded the Daughters of Charity (1633). In the following century Howard revealed deplorable conditions in nursing—filth, stealing, and ill treatment of patients. Theodor Fliedner, a 19th-century clergyman, later influenced reforms and emphasized citizens' responsibility for the health and welfare of people everywhere.

During the 19th century the movement for reform in nursing was led by Florence Nightingale, a woman of intellectual and moral power. Family contacts with humanitarian leaders and an education that included training in science, mathematics, and political economy were her preparation. She critically studied nursing as it was practiced in several countries, formulated her ideas, and wrote extensively.

The work of Florence Nightingale

In 1854 Florence Nightingale was asked by the British secretary of state at war to go to Scutari in Turkey, where absence of sewers and of laundering facilities, lack of supplies, poor food, disorganized medical service, and absence of nursing led to a death rate of more than 50 percent among wounded soldiers. Her work and that of the nurses whom she recruited brought sufficient improvement to lower the death rate to 2.2 percent. A gift of £45,000 was raised by popular subscription, and Florence Nightingale used it to establish schools of nursing at St. Thomas's Hospital in London and elsewhere.

Florence Nightingale believed nursing to be suitable as an independent career for capable, trained women, that nursing services should be administered by those with special preparation, and that relationships between physicians and nurses should be professional. She maintained that schools of nursing should be administered by nurses with physicians as part of the hospital labour force. She believed that there was a substantial body of knowledge and skills to be learned in nursing. Nurses were to be prepared for hospital nursing and care of the sick at home, and they were to teach good health practices to patients and families.

By the end of the 19th century, the idea that a nurse needed to be educated and trained had spread to much of the Western world. In England, Scandinavia, America, and much of the British Empire, schools of nursing were generally based on training hospitals, and more nurses had become independent of religious institutions. On the Continent, however, the Motherhouse system and religious organizations often persisted. With the foundation of the Red Cross in 1863, some national Red Cross societies undertook the training of nurses and provided instruction for auxiliaries to help in time of war or emergency.

With advances in medicine, nurses followed doctors into specialities, including pediatrics, surgery, orthopedics, ophthalmology, psychiatry, and public health. The development of physicians' assistants has sometimes overlapped with the development of nurse specialists, though efforts have been made to differentiate the two categories. Pediatric nurse-practitioners, for example, now undertake functions previously performed only by physicians—taking histories, performing physical examinations on children, and running clinics for mothers and babies. There has also been experimentation with shifts in functions from medicine to nursing.

Planning is aimed at bringing nursing resources into balance with the needs for nursing personnel to implement health programs. WHO has developed a guide for such planning, published in several languages; the guide helps countries to establish goals and avoid disadvantages of haphazard growth. Coordinated planning among the several health professions and occupations is now considered to be highly desirable.

THE PRACTICE OF NURSING

Methods of classifying nurses

Kinds of nursing. Nursing personnel and the kinds of nursing in which they engage may be classified in a variety of ways: by legal designation—registered nurses, licensed practical nurses, and, in addition, unlicensed nurses' aides; by the kind of educational preparation—vocational, technical, and professional, including graduate education—that they have received; by the kind of work they perform—institutional, community, educational, occupational, research, or journalistic; by the level of responsibility that they assume—that of staff nurse, teacher, supervisor, administrator, or consultant; and by the place of employment—hospital, physician's office, public health agency, school (school health nurses), industry, a school of nursing, including undergraduate and graduate programs. Nurses may also be classified as either generalists or specialists. Most descriptions of nursing, including the following, combine these classifications.

Hospital nursing. Hospital nursing occupies approximately two-thirds of the total nursing force in most countries. Nurses giving direct care to patients in hospitals of the United States, for example, include registered nurses, some of whom may be specialists; licensed practical nurses; and nurses' aides. Aides and sometimes practical nurses, if there are any, are called auxiliaries in many other developed countries. In large, highly organized hospitals, administrators of nursing services need special preparation and occupy demanding executive positions.

Certain areas of hospitals are highly specialized—surgical suites (operating rooms), recovery and intensive-care units, coronary-care units, and drug addiction clinics. In these, nurses giving direct patient care and their supervisors must have the additional preparation afforded by graduate study or by continuing education or staff-development (in-service-education) programs.

The rapid development of hospitals in response to advances in science and new community responsibilities requires new kinds of nursing. Some hospitals use nurse-midwives in maternity departments. Nurse specialists work in a number of other areas as well—medical, surgical, obstetric, pediatric, psychiatric, and rehabilitative; these

nurses frequently cross over to other fields as consultants. For example, public health nurses are employed to ease patients' adjustment to returning home and to assure planned continuity of health care. A few nurses occupy ombudsman, or patient-advocate, positions. Some others perform research aimed at solving problems and at devising improved ways of caring for patients.

New health problems bring additional responsibilities to nurses in hospitals. Drug abuse, family planning, and terminal illness, for example, are areas that call for specialized knowledge on the part of nurses, as well as for decisions about the organization of the services in hospitals.

Outpatient and home care

Outpatient and home care are sometimes organized by hospitals to reduce costly hospitalization for patients. Clinics in outpatient departments may be operated almost exclusively by nurses—clinics for hypertension (high blood pressure), chronic heart disease, and poststroke and maternity patients are examples. Satellite clinics bring services close to patients' homes. These expanded services require that nurses learn assessment methods—simple physical examination and history taking, for example—understand community problems and the organization of nursing services.

Efforts to return many patients of mental hospitals to their communities have met with some success. In some of these hospitals, as well as in community mental health centres, nurses with graduate degrees share in the treatment of patients and conduct group therapy.

Public health nursing. Public health, or community health, nursing may be either governmental or private. Visiting-nurse services care for the sick at home and carry on individual, family, and community programs of prevention and health teaching. These services are usually supported by civic and other forms of private philanthropy and by fees from patients who can afford to pay. Some of the visiting-nurse services have contracts with local government health and welfare agencies and with industrial health units to provide services. Many have deep, traditional roots in their communities.

Support

In 1978 WHO declared its goal of "health for all" by AD 2000, stressing the efficient and effective use of medical personnel and urging the greater use of nurses in primary care. WHO called for the reorientation of the basic nursing curriculum from an institutional to a community basis, concentrating on education and prevention. Many member states have made progress in that direction. Nursing schools in such countries as Chile, Colombia, Costa Rica, Cuba, Ecuador, Honduras, Indonesia, Nicaragua, Panama, Peru, the Philippines, and Thailand have increased their emphasis on the theory and practice of community health. Other member states, including several in Africa, have begun training for an expansion of nursing functions to strengthen primary health care services, producing nurse practitioners licensed for diagnostic and therapeutic activities, previously considered the domain of the physician, and the prescription of drugs. These functions are usually performed in health centres and in health posts within an organized administrative framework. In some countries nurses are often the only health professionals in isolated rural areas, and even in urban areas specially trained nurses can save the physicians' time and allow for the provision of better service.

Nurses as educators. Nursing education is a field that combines nursing with the teaching of students of nursing and, for some, with the administration of educational programs. A high proportion of the teachers in nursing-education programs teach in clinical situations, in which students learn to care for patients and families in hospitals, at home, and in other situations. Teaching by nurses in staff-development programs of hospitals and other health agencies and in continuing-education programs is usually offered by universities or associations.

Private, office, and industrial nursing. Private, office, and industrial (occupational health) nursing as fields of employment account for only a small percentage of registered nurses. Licensed practical nurses are also employed in these fields.

Military nursing. Military nursing provides an essential part of the health care given to men and women of the armed services in most countries. During World War I many of the trained nurses who were part of the military forces of the countries involved were drawn from a reserve maintained by the Red Cross. By the close of World War II much progress had been made in assigning nurses rank and responsibilities commensurate with their training and abilities. Medical corpsmen today save lives on battlefields and hospitals and are highly skilled. Some remain in health work after they leave military service.

Government nursing. This field includes military nursing and public health nursing as carried on by national and local health departments, functions discussed above.

Education. The basic educational program for nurses in many countries is both scientific and humanistic in content. In the United States most programs lead to the bachelor's degree. Nursing specialists, teachers, and other leaders in the field, however, may need advanced training at the master's or doctoral level. All educational programs include experience with patients in hospitals, homes, or other settings.

In almost all countries with nursing education there are at least two kinds of programs—those leading to diplomas and those that train auxiliaries, though a large portion of auxiliaries in some countries are untrained. A growing number of countries have one or more bachelor's degree programs; some have several. Among the latter are Australia, Canada, Colombia, Peru, Egypt, India, the Philippines, Taiwan, Thailand, the United Kingdom, and the United States. Master's degree programs have also been developed in several countries.

Countries with bachelor's degree programs

Post-basic programs for nurses with diplomas have been established in many countries. Some programs offer courses in general education, as well as nursing courses, and some, in universities, may become programs leading to a bachelor's degree. The purposes of such programs vary and include the preparation of teachers, supervisors, or administrators and of nurse specialists in various fields, including midwifery, public health, and teaching of auxiliaries. Some augment the education received in other programs. Enrollment is generally small in relation to the need for their graduates.

The development of nursing education in any country is affected by the developments in general education. In the United States and some other countries, for example, high school graduation or its equivalent has for many years been a requirement for admission to schools preparing registered nurses. In the United States this is also a requirement for admission to practical-nurse programs. In some countries fewer years of previous education are required.

Licensing and registration. After the number of nurses has become substantial and the essential nature of nursing has become established in a country, the need to regulate the practice of nursing under law becomes evident. These laws are aimed at the protection of the public.

Laws define nursing and establish titles under which nurses practice. Most laws establish boards empowered to give examinations and maintain registers of qualified nurses. Boards also are usually empowered to maintain lists of schools the graduates of which are eligible to take examinations. Further, the laws that regulate nursing usually provide ways to recognize licenses acquired by nurses from other states and countries.

The Nurses Act of 1919 established the General Nursing Council for England and Wales to maintain a register of nurses; similar acts were passed in 1919 for Scotland and in 1922 for Northern Ireland. The advent of the National Health Service (1946) called for enlargement of the council and its functions, and in 1949 an act was passed that consolidated all previous acts and established regional committees to work with schools of nursing for their improvement and for ways to meet new challenges.

In 1979 the Nurses, Midwifery and Health Visitors Act set up the Central Council for Nursing, Midwifery and Health Visiting and national boards for the four parts of the United Kingdom. The Central Council became responsible for the basic course, the registration of nurses, disciplinary machinery, and all post-basic education, including health visiting, district nursing, and school nursing.

In the United States, national and state nursing associa-

tions are prime movers in urging legislation for licensure and registration and in securing amendments. The American Nurses' Association gives leadership to state associations and state boards regarding changes in definitions, the desirable provisions of the law, and the legislative process.

The International Council of Nurses exerts leadership among national nursing associations in their efforts to pass and amend laws. The staff of the World Health Organization also has assisted new countries in the licensing process.

Organizations. Near the beginning of the 20th century, nurses began to organize national associations. The purposes of such organizations usually include the promotion of nursing care of high quality, promotion of desirable legislation in nursing and health, formulation of nursing and educational standards, professional development and welfare of nurses, and representation of nursing with other professional associations and government agencies. Many nursing associations publish professional journals. In large countries the national associations have state or provincial and district constituent associations.

An example of a thriving and vigorous national organization is the American Nurses' Association, founded in 1896, which operates aggressive programs. It affects legislation related to health and nursing in the U.S. Congress through its educational and lobbying activities and exerts leadership in the revision of state laws governing registration and the practice of nursing. A strong program for economic security has elevated nurses' salaries and the conditions of patient care, partly through collective bargaining. The official statements of the association set the course of action. Its official publication is the *American Journal of Nursing.* In England a large national nursing organization is the Royal College of Nursing.

The International Council of Nurses

In 1899 the International Council of Nurses was founded as a federation of autonomous national nursing associations. Today there are about 100 member associations from most major countries, and the council is working in other countries to assist in the development of national associations and ultimate membership in the council and to encourage national legislation on registration and nursing practice. An international congress is held every four years. The council's journal, *International Nursing Review,* makes a substantial contribution to worldwide literature of nursing. The Florence Nightingale International Foundation, which is related to the council, has conducted an international conference on research in nursing, as well as an international exchange of nurse scholars.

Several national colleges of nurse-midwifery and an international college work for the improvement of maternal and infant health. Nurses participate in international and national associations for public health, mental health, industrial health, and school health and in such areas as heart-disease, cancer, and respiratory-disease control. The Nursing Section of the American Public Health Association is one of its largest sections. Practical nurses and auxiliaries are usually organized, if at all, in separate organizations. Various groups form special organizations in several countries—deans of schools of nursing and surgical nurses are examples. Nursing councils are parts of regional commissions on higher education in the United States.

A unique organization—the National League for Nursing—combines nurses, related professionals, and other public-spirited citizens in the United States for meeting the nursing needs of people throughout the country. This organization also carries on a program of national accreditation of the various kinds of educational programs. Its journal is *Nursing & Health Care.*

ROLES OF INTERNATIONAL AND MULTINATIONAL ORGANIZATIONS

The International Red Cross. The International Red Cross plays two major roles in nursing: it affords educational opportunities for nurses, and it affords nurses opportunity to serve in programs embodying the Red Cross principles of humanity, impartiality, and neutrality. Through participation in Red Cross activities, public-spirited citizens acquire valuable knowledge of the health needs of people and how nursing helps to meet these needs. Also, nurses broaden their concepts of community and worldwide service.

Some national Red Cross societies operate schools of nursing, post-basic educational programs, and training programs for auxiliaries. In addition, many societies carry on programs preparing nurses to teach health practices in the home; this instruction reaches many thousands of people, who thus learn individual responsibility for health and the care of mothers and children and of patients suffering from simple illnesses. Many societies also train nurses to care for people in disasters and emergencies and deploy nurses to sites of emergencies when needed; some nurses volunteer to serve in emergencies that occur in other countries.

National Red Cross societies place emphasis on community development and youth programs. Societies are urged to be constantly alert to social changes, such as those resulting from urbanization, migration, or drug abuse, and to coordinate their efforts with other voluntary and official agencies. Nurses with knowledge of community conditions can and do contribute to planning and action through board and community memberships, as well as through their participation in the carrying out of Red Cross programs.

The World Health Organization. The World Health Organization has included nursing in its activities from its beginning in 1948. Nurses are included on teams such as those concerned with maternal and child health, malaria, and tuberculosis. Member nations request assistance in developing educational programs for nurses, auxiliaries, and midwives and to organize public health programs and hospitals.

WHO assistance

Countries are assisted in establishing nursing as a part of their national health departments to assure the planning and implementing of the nursing portions of programs. Governments are aided in the establishment of nursing and nursing-education systems, including those in midwifery. Other programs in which assistance is given include upgrading diploma schools; development of basic and post-basic programs in universities; revision of entry requirements; coordination of classroom teaching with the clinical practice of students; adaptation of hospitals and health agencies for students' experience; preparation of public health nurses, administrators, midwives, and teachers, including teachers of auxiliaries and of indigenous midwives. (In many countries more than half of all the births are attended by untrained midwives.)

Fellowships are granted to nurses for overseas study, mostly in the areas of teaching, administration, public health nursing, midwifery, maternal and child health, and for learning to plan health services. When consultants from the World Health Organization work in countries, they strive to leave national counterpart personnel to continue the work. Study outside the country may be needed to develop such personnel.

The European Economic Community. In countries of the European Economic Community, nursing is bound by the directives and regulations published by the Council of Ministers in 1977. The Permanent Committee of Nurses lays down broad guidelines for nurses' training and education and each country has a central authority, such as the Central Council of the United Kingdom. In 1979 the nursing directives required universal recognition of certificates and diplomas, and the European Economic Community countries now accept the competence of nurses trained in member states. Also established were a standard of general education to be attained before entry to a school of nursing, the number of hours the training must occupy, and the areas in which students must have theoretical and clinical knowledge. (L.P.Le./Ed.)

Dentistry

Dentistry is that profession concerned with the prevention and treatment of oral disease, particularly disease of the teeth and supporting tissues. In addition to general practice, dentistry includes many specialties and subspecialties, including oral surgery, prosthodontics, periodontics, orthodontics, pedodontics, and public health.

HISTORY OF DENTISTRY

Accounts of toothache and other oral complaints together with suggested forms of treatment have been found in some of the earliest texts of the ancient civilizations of the Middle and Far East, including China, Egypt, India, and Mesopotamia. Sumerian clay tablets probably of 5000–3000 BC record the belief, which persisted for several millennia, that dental decay and toothache were caused by the gnawing away of the tooth by a minute worm. In India a professional class of physicians who included dentistry in their activities described teething as a cause of serious infantile illnesses such as cough, diarrhea, vomiting, and convulsions, a myth that has persisted among some people to the present day.

Ancient remedies

In these early civilizations, a great variety of dental medications and operations, such as filling or extracting decayed teeth and the splinting of loose teeth or fractures of the jaws, were in use. In about 400 BC Hippocrates described many oral diseases, and he is credited by many with having introduced the term aphthae, which is still in use for the painful, but otherwise harmless, oral ulcers that occur particularly in adolescence or early adult life. Another observation made in ancient Greece, that sweet foods caused teeth to decay, was only experimentally confirmed in the 20th century.

Over the centuries many kinds of dental instruments and empirical forms of treatment developed, but dentistry remained essentially a craft included in the activities of surgeons or practiced by itinerant "healers." In the early 16th century in France, dentistry was practiced by barbers, and in England the Barber-Surgeons' Company (later to become the Royal College of Surgeons) was granted a charter by Henry VIII. Surgery and dentistry eventually passed out of the hands of barbers, and the 16th and 17th centuries saw the emergence of dentistry as a specialty with its own literature.

The first textbook in dentistry was published in Leipzig in 1530, and 50 years later students of dentistry were admitted to the University of France. By 1622 a number of men had been granted the title of surgeon-dentist, although the title was not fully established for a number of years after that. During the reign of Louis XIV, the surgeon-dentists formed a separate subdivision of the surgeons' guild and, the year after the subdivision was formed, it became law that those who wished to practice in the field of mouth surgery and artificial restoration had to pass prescribed examinations. At this time some women were permitted to practice dentistry in France, although the privilege was revoked during the mid-1700s.

In the 17th century in England dentistry was referred to as an independent specialty. The first English text on the subject of dentistry was published in 1685.

Textbooks

Publication of three highly significant textbooks occurred during the 18th century. The French dentist Pierre Fauchard's *Le Chirurgien Dentiste* ("The Surgeon Dentist") in 1728 put dental treatment on a more scientific plane than ever before and advocated a broader education for dentists. In 1756 the German dentist Philipp Pfaff's *Abhandlung von den Zähnen* ("Treatise on the Teeth") appeared, and in 1771 an anatomist and surgeon of England, John Hunter, who was giving lectures on dentistry, published *The Natural History of the Human Teeth*. Joseph Fox was appointed dental surgeon at Guy's Hospital in 1799, and at the same time lectures on dentistry were set up in Guy's and in a number of other areas.

The next major advance in dentistry was the introduction of general anesthesia to medicine by two dentists, Horace Wells and William Morton, between 1844 and 1846. In 1884 Sigmund Freud demonstrated the value of cocaine as a local anesthetic. William Stewart Halsted, a surgeon, carried out the first regional local anesthetic of the inferior dental nerve, using a technique that has remained essentially unchanged.

In 1890 W.D. Miller published his finding that teeth could be caused to decay, in vitro, by the action of mouth bacteria on carbohydrates. More than half a century was to elapse, however, before the bacterial basis for dental caries could be definitively established. Since the 1940s, dental research has increased in range and scale in all of its specialities. The result has been an increasing number of publications and journals and the formation of national and international research associations.

No formal dental schools were established in England until 1858, although dental hospitals had been established earlier. These dental hospitals, which were created as centres to serve the poor, were founded and supported by dentists. For the most part they were independent of medical schools and general hospitals. They did accept some students, however, who partly provided cheap labour to operate the hospital and whose fees were used to support the charitable work undertaken. The honorary dental surgeons were responsible for any teaching that was done. In 1858 the first dental school in the United Kingdom was established by the Odontological Society of London and the second school the following year by the College of Dentists of England. Both were private schools.

Early dental schools

At about the same time the Royal College of Surgeons arranged to hold examinations for licensure for dental surgery. It remained the examining body for dentistry in Great Britain for about 20 years. In 1878 the first Dentists' Act in the United Kingdom was passed and the General Medical Council established a register of those qualified to hold the title of dental surgeon. The act did not, however, prohibit individuals without these qualifications from practicing. The General Medical Council also prescribed a curriculum for the training of dentists. It required two years of preceptorship to learn dental mechanics and three years in a medical school and dental hospital. An inspector of the examination procedures at the colleges in 1897 recommended that the one examination be replaced by three—in preliminary science and dental mechanics and a final examination. These recommendations were put into effect and remained without much alteration until 1922.

Early dentistry in the United States

While schools were being established and standards for licensure created in England, development had also been going on in North America. Dentistry was being practiced in the United States by the late 1790s, and the first textbooks appeared in the early 1800s. By 1834, when the first meeting of a dental society in the United States was held, services were being provided by three distinct classes of people. First, there were those who had qualified by a course of study in the principles of medicine and surgery. Second, there were those who had obtained a preparatory course of medical study and then begun practicing dentistry without having studied the mechanics of dental operations. These people were held in comparative respect since in due course they did obtain some degree of skill in their operations, although they were criticized for not having obtained this skill before actually inflicting their services on the public. The third group included a great number of charlatans—anyone who decided he would like to practice dentistry. It is this group that brought dentistry into disrepute.

During the 1830s two unsuccessful attempts to establish dental schools were made, the first in Kentucky and the second in New York City. The latter failed to get under way because of staff problems. No money was available at that time for salaries, and local dentists evidently felt that they could not spare time from their practice for teaching.

The first dental school in North America was established in Baltimore in 1840. Subsequently many other schools were started, many of which were operated privately or commercially. All of the early schools were separate from universities. The first, and for many years the only, school of dentistry in the United States associated with a university was opened at Harvard in 1867.

This was also the era during which dentistry became organized in Canada. The first dental act in Canada was passed by the legislature of the Province of Ontario in 1868. This act incorporated the Royal College of Dental Surgeons of Ontario and gave it the dual function of teaching and licensing. License requirements stipulated five years of practice in a dental office for registration. Except for a simple act that was passed in Alabama in 1841, the Ontario Act was the first law respecting dental practice in North America. The regulations for registration were fairly simple by today's standards, but with the large number of itinerant dentists, who had no formal training

whatever, moving back and forth across the Canadian-U.S. border at that time, even this five-year requirement proved useful.

THE PRACTICE OF DENTISTRY

Licensure requirements. The practice of dentistry is now well controlled, and in all countries of the world in which dentistry is practiced there is a licensing requirement. The licensing authority may be the government or national dental organizations.

Canada. In Canada each province has its own licensing authority. This can be a college, such as the Royal College of Dental Surgeons of Ontario, or an association, such as the Manitoba Dental Association. There is also a national authority, the Dental Examining Board.

The university degree (doctor of dental surgery or doctor of dental medicine) does not in itself entitle the holder to practice but is an academic qualification for presentation to the licensing board under whose jurisdiction the holder wants to obtain a license to practice. The regulations of the provincial licensing boards vary but usually require an examination for licensing.

United States. Licensing authority in the United States is vested in state boards of dental examiners, most of which require an examination. Most states require U.S. citizenship as a prerequisite. Some states require non-citizens to submit the declaration of intent to become a citizen or the first papers as a requirement for admission to the dental licensure examination; a few do not require citizenship for such admission.

Nationals with foreign diplomas may be admitted to practice if their diplomas were issued by a school approved by the American Dental Association and if they pass the state licensure examination.

Soviet Union. Dentists in the former Soviet Union were divided into three distinct classes, known as two-, three- and five-year dentists. The two-year dentists were dental technicians who studied for two years beyond secondary school, after which they became eligible to work in a dental laboratory. Two-year dentists were not permitted to treat patients. The three-year dentists were permitted to treat patients, but their practice was limited to restorative, prosthetics, and prophylactic dentistry. The five-year dentists were stomatologists, who were on a par with physicians in the Soviet Union. They received training equal to that of physicians and, in addition, were trained in operative dentistry, crown and bridge dentistry, prosthetics, exodontia, and anesthesia, both general and local. The five-year dentist's degree entitled the practitioner to perform surgery on the hard as well as all soft tissues in the mouth and throat.

European Economic Community. With the advent of the European Economic Community and the Council of Europe, it has become accepted policy that doctors and dentists should be able to move freely and practice within any of the member countries. For this to be acceptable there has had to be mutual recognition of dental degrees and comparable forms of qualification. The Council of the European Communities has, therefore, agreed on a set of directives that set out the training requirements for dental education in the member states. This has created no difficulties for most European countries, where dentistry has long been recognized as a specialty in its own right. In Italy and Spain, however, where dentistry is a subspecialty of medicine, transitional provisions have had to be made until dental training can be harmonized with that of other member states.

Permission to practice in the United Kingdom is granted by the General Dental Council to those holding (1) a degree or diploma in dentistry or dental surgery conferred in Great Britain or Northern Ireland, (2) a degree or diploma in dentistry or dental surgery granted elsewhere that has been recognized by the General Dental Council, or (3) a degree or diploma approved by the General Dental Council provided that these graduates have passed the statutory examination written under arrangements made by the General Dental Council.

Dentists in Germany must hold a dental surgeon's diploma, which authorizes private practice without further examination. They must be registered by local dental boards and by health authorities.

In Italy a diploma in dentistry, which allows the use of the title of Specialist in Diseases of the Mouth, Teeth, and Jaws, constitutes a license to practice. Holders of the diploma of Doctor of Medicine have passed examinations in dentistry and for this reason may also practice dentistry but do not have the specialist title.

Japan. Since about 1903 Japanese dentistry has been mainly patterned after that practiced throughout the United States. Those wanting to practice dentistry or dental surgery must be recognized by the national government. Applicants for registration must pass the national examination for dentists and obtain license to practice. These requirements must also be fulfilled by registered medical practitioners wanting to practice dentistry, by Japanese citizens, and by foreigners who have qualified in Japan.

Types of practice. *Private practice.* In Canada, the United States, the United Kingdom, and Australia, dentists in private practice constitute the vast majority of all licensed dentists. The situation is much the same in France and various other countries.

Dental practice has changed significantly since 1920, without a concurrent change in the basic dental curriculum. Dental procedures have shifted from the repair and extraction of teeth for the relief of pain in 1920 to prevention of disease. Dental practice has also changed in larger urban centres from the isolated private practice common in 1920 to a complex system of groups of professionals in a central location. Extensive use is now made of dental hygienists, who often receive the patient from the examining dentist. Dental hygienists provide services such as preventive procedures, prophylaxis, scaling, X rays, and dental health education. Most practices also use dental assistants.

Shift from individual to group practice

Another development that has occurred in dental health-care services is the extension of the duties currently carried out by dental auxiliaries. New Zealand has pioneered in the field with the creation of the dental nurse, an auxiliary who is trained to provide dental care for children without the supervision of a dentist. The United Kingdom has also developed the "dental auxiliary," who performs somewhat similar duties but under closer supervision. In Canada and the United States, pilot projects have been conducted to test the feasibility of using dental auxiliaries for certain operative procedures in order to increase productivity, quality, and general service to the public.

France may be taken as an example of the development of the practice of dentistry in continental Europe. There are two types of dentists practicing in France, the *chirurgien dentiste* and the stomatologist. The practice of dentistry in France by a *chirurgien dentiste* has, since 1892, been restricted to persons of French nationality who hold a state diploma and who are registered with the Order of Dentists. The Order of Dentists is responsible for registration and discipline but is not concerned with dental education, which is controlled by the state through the common state diploma.

Stomatologists are practitioners who have a diploma in medicine together with either a diploma in dental surgery or a certificate of special studies (two years) in stomatology. Specialization within the field of dentistry is not encouraged. There are no rules laid down for it nor are there any special courses or diplomas or titles.

Hospital dental practice. Three types of dental care are normally carried out in the hospital environment: (1) clinical procedures normally provided in a dental office, for ambulatory inpatients and outpatients, (2) bedside care for persons admitted for other medical reasons, and (3) inpatient care for patients admitted to a hospital for purely dental conditions.

Types of dental care

Dentists may treat patients in hospitals either privately, on a fee-for-service basis, or under some form of government program, such as the National Health Service in the United Kingdom or the Provincial Medicare Plan (surgery only) in Canada. Hospital dental services have for years been an integral part of dental health care and dental education in the United Kingdom, and such services by hospital dental departments have expanded steadily in the United States and Canada.

Hospital dental departments are normally established in the same manner as any other hospital department and are headed by a chief of service, who has the same status as other chiefs of service within the hospital. In some instances, the chief of the dental department may be responsible to the chief of surgery. There are two types of hospital dental departments—one that is established in a teaching hospital and the other in a general hospital with no teaching component. In the teaching hospital the dental department is associated with a faculty of dentistry and forms an integral part of the undergraduate curriculum and, if they exist, of the graduate and postgraduate programs. One of the chief purposes of hospital dental departments is to make available the service of consultants to other hospital departments and general practitioners. This service is most highly developed in teaching hospitals. Usually, certain general dental treatment is provided for inpatients and outpatients. Hospital dental services or departments are prevalent in western Europe.

Public health practice. Generally typical of dental public health practice in Canada and in many areas of the United States is the program carried on in Ontario. There dentists trained in public health, hygienists, and dental assistants carry out a preventive and educational program basically concerned with the examination of children, the recording of basic dental conditions, and the provision of dental health education.

Military practice. Most countries of the world provide dental-care service for their armed forces. The organization of such a service varies extensively. In Canada the Royal Canadian Dental Corps has the same status as the Royal Canadian Medical Corps, with a brigadier general as the director. Military service for dentists in the United States is under the U.S. Public Health Service, the chief of service being an assistant surgeon general. In the United Kingdom dental care is provided by three separate dental branches—Navy, Army, and Air Force.

Governmental practice. In many countries dentists are required to work a number of years for the government before they may be considered private practitioners of the type known in Canada and the United States. This service requirement may be based on the fulfillment of an obligation for government financial support during undergraduate training, or there may be a government regulation that all dental graduates must work for the state for a prescribed number of years. Another example of government practice is in the United Kingdom, where dentists are employed by local authorities to provide dental care under the Maternal and Child Welfare Services and the School Dental Service.

The employment of dentists on a salary basis for the general practice of dentistry is not extensive in the United States or Canada. At the national level it may be the provision of dental care for eligible Indians and Eskimos, war veterans, or inmates of penitentiaries. At a municipal level, dentists may be employed in a school dental service. Dentists in both Canada and the United States commonly agree to provide service for families who qualify for social assistance. They are paid on a fee-for-service basis; the fee schedule is usually set, normally after consultation with the profession, by the agency responsible for the social service plan.

Government medical care was introduced in Japan in the late 1930s. This system was expanded until by 1962 almost the entire population was covered. There are limitations to the services offered by government medical care, as in orthodontics or in preventive dentistry.

The status of the specialist

Dental specialties and subspecialties. In most countries that recognize specialties in dentistry, the specialist is limited to practice in the specialty and cannot carry out the practice of general dentistry. Where the specialty is thus limited the general dentist may refer patients, and a specialist's practice is mainly on a referral basis. In Britain and in certain provinces in Canada, specialists may conduct a general practice.

Orthodontics. Orthodontics takes as its aims the prevention and correction of malocclusion of the teeth and associated dentofacial incongruities. Orthodontics has been practiced since the days of the ancient Egyptians, but methods of treatment involving the use of bands and removable appliances have become prominent only since the beginning of the 20th century. The United States gave impetus to the development of orthodontics, which was recognized as a specialty with the formation of the American Society of Orthodontists in 1900.

The demand for this service extends from the child to the mature adult, although human bone responds to tooth movement best in a person under 18, and it is generally agreed that children benefit more from treatment than do adults. In general, oral health and physical appearance are the two most important reasons for undertaking a course of orthodontic care.

Dental care for children

Pedodontics. Pedodontics, analogous to pediatrics in medicine, is concerned with the dental care of children and adolescents.

Much of the routine of practice is centred around the control of caries (tooth decay) and involves the use of fluoride and dietary and hygienic instruction. The need to influence tooth positions presents the next most frequently encountered problem. The correction of incipient abnormalities in tooth alignment may obviate the necessity for lengthy treatment. Many pedodontists use growth-influencing techniques to correct jaw alignments. A working knowledge of children's behaviour patterns, patience, and a knowledge of childhood physical and mental diseases and their ramifications are important qualifications of the pedodontist.

Periodontics. Periodontics is concerned with the prevention, diagnosis, and treatment of diseases of the periodontal tissues—the tissues that surround and support the teeth. These tissues consist mainly of the gums and the jaw bones and their related contiguous structures.

The most prevalent periodontal disease is periodontitis, commonly called pyorrhea, an inflammatory condition usually produced by local irritants. Periodontitis, if untreated, destroys the periodontal tissues and is a major cause of the loss of teeth in adults.

The advances of periodontics have been mostly in techniques of treatment. It is believed that bacterial plaque, a soft layer of substances rich in bacteria that adheres to the teeth, is the factor responsible for most destruction of the gums and the tissues surrounding the teeth. Periodontists advocate removal of such plaque by a specific regimen of controlled hygiene.

Prosthodontics. Prosthodontics is concerned with the restoration and maintenance of oral function, comfort, appearance, and health by the replacement of missing teeth and contiguous tissues with artificial substitutes, or prostheses.

Branches of prosthodontics

There are three main branches of the specialty, concerned, respectively, with removable prostheses, fixed prostheses, and maxillofacial prostheses. Maxillofacial prostheses are supplied to persons who have suffered congenital, traumatic, or surgical defects of the mouth, jaws, or associated facial structures.

The proper fitting of oral prostheses requires a detailed knowledge of the anatomy of the head and neck, of the physiology of the neuromuscular system, and of the science of occlusion and jaw movements. It also requires skill in planning, mouth preparation, impression making, registration of jaw relations, try-in procedures, placement of the prostheses, and follow-up care.

Oral medicine. Oral medicine, or stomatology, treats the variety of diseases that affect both the skin and the oral mucous membranes. Some of these diseases, such as pemphigus vulgaris, can develop their first manifestations in the mouth and can be life-threatening. Cancer of the mouth also has a high mortality rate, partly because it grows in such close proximity to so many vital structures and readily involves them. With all such diseases of the oral cavity, removal of a portion of the lesion for examination under the microscope (biopsy) by an oral pathologist is an essential procedure, and many other laboratory procedures are often also required for the diagnosis of oral mucosal diseases.

Oral pathology. Oral pathology is the study of the causes, processes, and effects of oral disease, together with the resultant alterations of oral structure and functions.

The oral pathologist provides diagnoses on which treatment by other specialists will depend.

Oral surgery. Oral surgery deals with the diagnosis of, and the surgery required by, the diseases, injuries, and defects of the human jaws and associated structures. Both dentists and physicians refer a wide variety of special dental problems to the oral surgeon. These may include the removal of impacted and infected teeth and the treatment of cysts, tumours, lesions, and infections of the mouth and jaws. In addition there are more complex problems, such as jaw and facial injuries, cleft palate, and cleft lip.

Public health dentistry. Dental public health is recognized as a specialty in Canada and the United States. The American Dental Association recognizes dental public health as a specialty if the holder of the master's degree proceeds to a further year of study in training and passes the examination of the American Board of Dental Public Health. Training in dental public health is available in the United Kingdom, but the specialty is not emphasized to the same degree in the rest of the world.

Forensic dentistry. Forensic dentistry is the study and practice of aspects of dentistry that are relevant to legal problems. It is a specialty practiced by few and is not usually part of dental education. Forensic dentistry is, however, of considerable legal importance for several reasons, one of the most important of which is the fact that the teeth are the structures of the body most resistant to fire or putrefaction. Moreover, the arrangement of the teeth or any restoration in them is virtually or completely unique to any given individual and, if dental records can be found, may enable identification with certainty similar to that provided by fingerprinting. The identification of human remains after aircraft accidents, for example, can often be made only by this means. Minor irregularities of the teeth can also be reproduced in bite marks, enabling a suspect to be identified if he has bitten another person.

Dental education. *Predental programs.* In a majority of countries in the world undergraduate training in dentistry is available. Many require predental training prior to acceptance into a school of dentistry. The predental training is in addition to primary and secondary education, which usually takes from 10 to 12 years. The required number of years in predental education varies from one to seven (a number of European countries require from five to seven years of medical education before entering dentistry). Predental course training usually includes such studies as biology, chemistry, physics, and mathematics. Certain faculties of dentistry in Canada and the United States require a bachelor's degree in arts or science as a prerequisite for admission into a dental faculty.

Dental school and training. After predental courses, training consists of four years in a faculty of dentistry to qualify as a doctor of dental surgery (D.D.S.) or doctor of dental medicine (D.M.D.). The program of studies during the four-year course includes the following biological sciences: human anatomy, biochemistry, bacteriology, histology, pathology, pharmacology, microbiology, and physiology, upon which the succeeding studies of the theory and techniques of dental practice are based. Studies required with respect to dental practice include restorative dentistry, prosthetics, orthodontics, surgery, preventive dentistry, medicine, dental public health, pedodontics, periodontics, radiology, clinical practice, and anesthesia.

ANCILLARY DENTAL FIELDS

Dental hygienists. The hygienist is a figure in the campaign to reduce periodontal disease and to improve physical well-being by promoting better care of the mouth.

Chief function of hygienists

The prevention of oral disease through education and treatment is the chief function of hygienists. The specific duties and services that they are allowed to perform depend on the bylaws of the licensing bodies, the requirements of the dental offices in which they are employed, or the aims and objectives of the public health programs in which they are engaged. At all times hygienists work under the effective supervision of a qualified dentist, and they are not permitted to establish their own practice.

Hygienists employed in dental offices remove deposits and stains from the patient's teeth, apply fluorides, and observe and record conditions of decay and disease for the dentist's information. Further duties may include the taking of X-ray photographs of parts of the mouth, which the hygienist develops and mounts. Another function of the hygienist is to promote dental health by advising on diet and nutrition and encouraging oral hygiene.

Hygienists employed by educational authorities assist school dentists by performing such duties as examining children's teeth. They may also visit classrooms to explain the importance of oral hygiene and to give instruction in the proper care of the teeth and gums. In hospitals they perform mainly the same duties as for private practitioners.

Dental nurses and dental auxiliaries. In New Zealand an auxiliary known as the dental nurse has been carrying out a dental-care program for children for a number of years. The dental nurse receives minimal supervision but is equipped to provide a dental-care program for children up to 13 years of age. The dental nurse is trained for two years in a special course for dental nurses with entrance requirements below the university level.

Training and functions of dental nurses

Dental assistants. The majority of dentists in private practice employ one or more dental assistants to provide such services as the reception of patients, the keeping of records and accounts, assistance for the dentist while he is treating patients, general upkeep of the office, developing of dental X rays, and sterilization of instruments.

Dental technicians and dental mechanics. Dental technicians, also called dental mechanics, make artificial crowns, bridges, dentures, and other dental appliances according to dentists' specifications. Work orders, accompanied by models or impressions of patients' mouths, state the exact requirements for each particular job. In large laboratories the various stages of manufacture are often divided and the technicians employed may specialize. Sometimes partially skilled persons are hired to work in limited aspects of production on an assembly-line basis.

ORGANIZATIONS

Associations of dentists, dental journals, and dental schools now exist in almost every country of the world. The Fédération Dentaire Internationale (International Dental Federation) was founded in 1900 and has met annually except in times of war. It has sponsored international dental congresses that are planned to meet every five years. Other international organizations include the International Association for Dental Research (Association Internationale pour la Recherche Dentaire) and the Association pour les Recherches sur les Paradentopathies (Association for Research into Periodontal Diseases), which was organized in 1932. *The International Dental Journal,* published by the Fédération Dentaire Internationale, was founded in 1950.

Within the general framework of the World Health Organization, the dental health program has progressed steadily from the beginning. A proposal for a joint review of stomatology and dental hygiene in collaboration with the International Dental Federation was made at the first World Health Assembly in 1948.

Certain organizations, including the World Health Organization and Fédération Dentaire Internationale, and countries such as New Zealand and the United States offer direct and financial assistance to many developing countries in the development of health educational and dental care services. For example, New Zealand has long provided developing countries with the benefit of its experience in the use of dental auxiliaries or what is commonly known as school dental nurses. Direct assistance is provided in the development of other public health dental services to countries such as Sri Lanka, Malaysia, Singapore, Brunei, Thailand, Indonesia, Hong Kong, and Papua New Guinea. Dentists from these countries have had the opportunity of studying the New Zealand system and a number of school dental nurses have received their training there, enabling them to assist in the establishment of their own training facilities. Pharmacy

Pharmacy is the science and art concerned with the preparation and standardization of drugs. Its scope includes the

cultivation of plants that are used as drugs, the synthesis of chemical compounds of medicinal value, and the analysis of medicinal agents. Pharmacists are responsible for the preparation of the dosage forms of drugs, such as tablets, capsules, and sterile solutions for injection. They compound physicians', dentists', and veterinarians' prescriptions for drugs. The science that embraces knowledge of drugs with special reference to the mechanism of their action in the treatment of disease is pharmacology.

HISTORY OF PHARMACY

The beginnings of pharmacy are ancient. When the first person expressed juice from a succulent leaf to apply to a wound, this art was being practiced. In the Greek legend, Asclepius, the god of the healing art, delegated to Hygieia the duty of compounding his remedies. She was his apothecary or pharmacist. The physician-priests of Egypt were divided into two classes: those who visited the sick and those who remained in the temple and prepared remedies for the patients.

Ancient and medieval pharmacy

In ancient Greece and Rome and during the Middle Ages in Europe, the art of healing recognized a separation between the duties of the physician and those of the herbalist, who supplied the physician with the raw materials from which to make medicines. The Arabian influence in Europe during the 8th century AD, however, brought about the practice of separate duties for the pharmacist and physician. The trend toward specialization was later reinforced by a law enacted by the city council of Bruges in 1683, forbidding physicians to prepare medications for their patients. In America, Benjamin Franklin took a pivotal step in keeping the two professions separate when he appointed an apothecary to the Pennsylvania Hospital.

The development of the pharmaceutical industry since World War II led to the discovery and use of new and effective drug substances. It also changed the role of the pharmacist. The scope for extemporaneous compounding of medicines was much diminished and with it the need for the manipulative skills that were previously applied by the pharmacist to the preparation of bougies, cachets, pills, plasters, and potions. The pharmacist continues, however, to fulfill the prescriber's intentions by providing advice and information; by formulating, storing, and providing correct dosage forms; and by assuring the efficacy and quality of the dispensed or supplied medicinal product.

THE PRACTICE OF PHARMACY

Education. The history of pharmaceutical education has closely followed that of medical education. As the training of the physician underwent changes from the apprenticeship system to formal educational courses, so did the training of the pharmacist. The first college of pharmacy was founded in the United States in 1821 and is now known as the Philadelphia College of Pharmacy and Science. Other institutes and colleges were established soon after in the United States, Great Britain, and continental Europe. Colleges of pharmacy as independent organizations or as schools of universities now operate in most developed countries of the world.

The course of instruction leading to a bachelor of science in pharmacy extends at least five years. The first and frequently the second year of training, embracing general education subjects, are often provided by a school of arts and sciences. Many institutions also offer graduate courses in pharmacy and cognate sciences leading to the degrees of master of science and doctor of philosophy in pharmacy, pharmacology, or related disciplines. These advanced courses are intended especially for those who are preparing for careers in research, manufacturing, or teaching in the field of pharmacy.

The basic five-year curriculum

Since the treatment of the sick with drugs encompasses a wide field of knowledge in the biological and physical sciences, an understanding of these sciences is necessary for adequate pharmaceutical training. The basic five-year curriculum in the colleges of pharmacy of the United States, for example, embraces physics, chemistry, biology, bacteriology, physiology, pharmacology, and many other specialized courses. As the pharmacist is engaged in a business as well as a profession, special training is provided in merchandising, accounting, computer techniques, and pharmaceutical jurisprudence.

Licensing and regulation. To practice pharmacy in those countries in which a license is required, an applicant must be qualified by graduation from a recognized college of pharmacy, meet specific requirements for experience, and pass an examination conducted by a board of pharmacy appointed by the government.

Pharmacy laws generally include the regulations for the practice of pharmacy, the sale of poisons, the dispensing of narcotics, and the labeling and sale of dangerous drugs. The pharmacist sells and dispenses drugs within the provisions of the food and drug laws of the country in which he practices. These laws recognize the national pharmacopoeia (which defines products used in medicine, their purity, dosages, and other pertinent data) as the standard for drugs. The World Health Organization of the United Nations began publishing the *Pharmacopoeia Internationalis* in the early 1950s. Its purpose is to standardize drugs internationally and to supply standards, strengths, and nomenclature for those countries that have no national pharmacopoeia.

Research. Pharmaceutical research, in schools of pharmacy and in the laboratories of the pharmaceutical manufacturing houses, embraces the organic chemical synthesis of new chemical agents for use as drugs and is also concerned with the isolation and purification of plant constituents that might be useful as drugs. Research in pharmacy also includes formulation of dosage forms of medicaments and study of their stability, methods of assay, and standardization.

Bioavailability

Another facet of pharmaceutical research that has attracted wide medical attention is the "availability" to the body (bioavailability) of various dosage forms of drugs. Exact methods of determining levels of drugs in blood and organs have revealed that slight changes in the mode of manufacture or the incorporation of a small amount of inert ingredient in a tablet may diminish or completely prevent its absorption from the gastrointestinal tract, thus nullifying the action of the drug. Ingenious methods have been devised to test the bioavailability of dosage forms. Although such in vitro, or test-tube, methods are useful and indicative, the ultimate test of bioavailability is the patient's response to the dosage form of the drug.

Licensing systems for new medicinal products in Europe and North America demand extensive and increasingly costly investigation and testing in the laboratory and in clinical trials to establish the efficacy and safety of new products in relation to the claims to be made for their use. Proprietary rights for innovation by the grant of patents and by the registration of trademarks have become increasingly important in the growth of the pharmaceutical industry and its development internationally.

The results of research in pharmacy are usually published in such journals as the *Journal of Pharmacy and Pharmacology* (London), the *Journal of the American Pharmaceutical Association* and the *Journal of Pharmaceutical Sciences* (Washington, D.C.), the *American Journal of Pharmacy* and the *American Journal of Hospital Pharmacy* (Philadelphia), and the *Pharmaceutica Acta Helvetiae* (Zürich).

ORGANIZATIONS

There are numerous national and international organizations of pharmacists. The Pharmaceutical Society of Great Britain, established in 1841, is typical of pharmaceutical organizations. In the United States the American Pharmaceutical Association, established in 1852, is a society that embraces all pharmaceutical interests. Among the international societies is the Fédération Internationale Pharmaceutique, founded in 1910 and supported by some 50 national societies, for the advancement of the professional and scientific interests of pharmacy on a worldwide basis. The Pan American Pharmaceutical and Biochemical Federation includes the pharmaceutical societies in the various countries in the Western Hemisphere.

International organizations

There are also other international societies in which history, teaching, and the military aspects of pharmacy are given special emphasis. (J.C.K./Fr.H.)

LEGAL ASPECTS OF MEDICINE

Maintenance of professional standards

HISTORY

Physicians historically have set their own standards of care and their conduct has usually been judged by comparing it to that of other physicians. "Ethical" canons or codes generally focused on professional etiquette and courtesy toward fellow physicians rather than on relationships with patients. The Hippocratic oath was a notable exception, but its provisions were only ascribed to by a minority of Greek physicians.

The law has become intimately involved in medical practice only in the 20th century. Until recently legal medicine, or forensic medicine, was a field devoted exclusively to the uses of medicine in the courtroom, primarily in two settings: forensic pathology and forensic psychiatry. The pathologist has traditionally been asked to determine and testify to the cause of death in cases of suspected homicide and to aspects of various injuries involving crimes such as assault and rape. Pathological testimony may also be required in civil cases involving, for example, occupational injury, negligent injury, automobile accidents, and paternity suits. Similarly, when a defendant pleads insanity as a defense, a psychiatrist is asked to examine the defendant and to testify as to his mental state at the time of the crime. The relevant question is usually whether his criminal behaviour was the product of a mental illness or whether the defendant was able to distinguish right from wrong. In civil cases, psychiatrists frequently appear as witnesses in cases of child custody and involuntary commitment.

Changes since 1960

Since 1960 the legal climate has changed drastically. Civil lawsuits alleging medical malpractice have become a fact of professional life for many Western physicians. Issues formerly relegated to ethics, such as abortion and termination of treatment, also have become important civil rights issues in courtrooms across the world, as have issues of informed consent and patients' rights. Wide-ranging campaigns aimed at arresting the spread of infectious diseases, such as acquired immune deficiency syndrome (AIDS), have involved the legal system in issues of privacy, confidentiality, quarantine, and research using human subjects.

So great has the change been that forensic medicine has now become a subspecialty of a separate field, usually called health law to emphasize its application not only to medicine but to health care in general. This new field of health law is not limited to the courtroom but is active as well in legislatures, regulatory agencies, hospitals, and physicians' offices.

RELATIONSHIP OF LAW AND ETHICS

The legal philosopher Lon Fuller has distinguished between "the morality of aspiration" and "the morality of duty." The former may be denoted ethics, the latter law. Ethics tells people what they should do and embodies the ideals they should strive to attain. Unethical behaviour leads to punishments that are related to how an individual is perceived, both by himself and by his fellow man. Law, on the other hand, provides boundaries of actions, set by society, beyond which a person may go only by risking external sanctions, such as incarceration or loss of a medical license.

The Hippocratic oath

This may explain why ethical codes usually involve generalities, while laws tend to be more specific. For example, the Hippocratic oath, formulated in the 5th century BC, is concerned with the physician's doing no harm, refraining from performing abortions and giving deadly drugs, and maintaining strict confidentiality. Law, on the other hand, may permit abortions under certain circumstances, permit the giving of potentially lethal drugs in extreme situations, and sanction the violation of confidentiality when the interests of society demand it.

For example, in treating a patient with AIDS, a physician might administer a potentially fatal experimental drug in a desperate attempt to destroy the retrovirus that causes AIDS. The physician might also warn the patient's spouse that there is a danger that the virus will be transmitted, even if the patient does not want the spouse to be so informed. These scenarios present ethical dilemmas, and it is unlikely that any of these actions would have legal consequences today.

Although the Hippocratic oath has largely been superseded by such modern oaths as the Declaration of Geneva, the International Code of Medical Ethics, and the Canons of the American Medical Association, these codes of conduct retain the brevity and generality of the Hippocratic oath. For example, the International Code of Medical Ethics, developed and promulgated by the World Medical Association shortly after World War II, provides in part for the following:

> A doctor must always maintain the highest standards of professional conduct.
>
> A doctor must practice his profession uninfluenced by motives of profit. . . .
>
> A doctor must always bear in mind the obligation of preserving human life. . . .
>
> A doctor shall preserve absolute secrecy on all he knows about his patient because of the confidence intrusted in him.

Effects of modern technology on ethics

Modern advancements in the field of medicine, such as cardiopulmonary resuscitation (which restores regular rhythm to an arrhythmic or failed heart) and mechanical respirators (which breathe for patients unable to expand their lungs) sometimes have been able to postpone a death that previously had been imminent. Under these circumstances, it may be difficult to relate the rules of ethics to the realities of the situation. For example, the meaning of "obligation of preserving human life" becomes unclear in the context of a young woman in a permanent coma who will probably die if the mechanical respirator is removed, but who may live for decades (in a coma) if the machine remains in place. It is not clear that the Hippocratic ideal of doing "no harm" requires that the machine remain in place or that it be removed.

In 1976 these same questions were confronted by the New Jersey Supreme Court in the landmark case of Karen Ann Quinlan. Her parents requested her physicians to remove the mechanical respirator in order to let their daughter die a natural death. The doctors refused, relying primarily on medical ethics, which they believed prohibited taking an action that might lead to the death of the patient.

In court, however, the lawyers for the Quinlan family argued that what was at stake was not medical ethics but the legal rights of the individual patient to refuse medical treatment that was highly invasive and offered no chance for a cure. The court agreed that patients have the legal right to refuse medical treatment, determined that honouring such a refusal was consistent with medical ethics, and decided that the parents of Karen Ann Quinlan could exercise her right to refuse treatment on her behalf. In order to reassure the physicians involved, however, the court also decreed that if a hospital's ethics committee agreed with the prognosis of permanent coma, the removal of the respirator could take place and all parties involved would have legal immunity from civil or criminal prosecution. Karen Ann Quinlan's respirator was removed, although she continued to breathe on her own. She survived in a coma until she died of pneumonia almost 10 years later.

The case of Karen Ann Quinlan has become a parable of modern medicine and of the relationship between medical ethics and the law. Although an issue was made of medical ethics by both the physicians and the court, the case primarily involved medical practice and the fear of potential legal liability. Modern physicians now also worry about the law as well as ethics, and they fear criminal lawsuits that allege homicide or assisting suicide, and civil lawsuits that allege malpractice. To address these concerns, the New Jersey court created an ethics committee with the power to grant legal immunity for actions and to diffuse the responsibility for them.

Ethics committees

This model has not been followed by other courts, however, although ethics committees have been established

in North America, Europe, and Australia to help educate hospital staffs on such matters as the withholding and withdrawing of treatment and on general ethical conduct with patients. In fact, physicians are rarely taken to court on criminal charges for decisions about patient care that are made in good faith. The Massachusetts Supreme Court, for example, has summarized the criminal law in this regard: "Little need be said about criminal liability: there is precious little precedent, and what there is suggests that the doctor will be protected if he acts on a good faith judgment that is not grievously unreasonable by medical standards."

In the United States, the Quinlan rationale has been expanded to include the right of all mentally competent patients, whether terminally ill or comatose, to refuse any and all medical treatments (including artificial feedings). Some people state their wishes about treatment in documents called "living wills," to which physicians can refer after the patient is no longer able to speak for himself. People also may provide someone with power of attorney to make decisions about medical treatment once they become incompetent to act on their own behalf. The American Medical Association has stated that honouring patients' refusals of treatment is consistent with both medical practice and medical ethics. Other countries, like The Netherlands, have gone further and have held that it is legally and ethically acceptable for physicians to assist a patient with a terminal illness in his decision to die by providing lethal injections.

While ethics and law are concerned with different concepts of right and wrong, in medicine they find common ground in their fundamental principles. Both law and ethics in medicine rest on the principle of self-determination by competent individuals, beneficence (or at least nonmaleficence) on the part of medical practitioners, and a concept of justice as fairness to be afforded to all patients by both medical practitioners and society.

Law and medical practice

The law indirectly influences medical practice by structuring the delivery and financing of medical services and it does so directly in three major ways: licensure requirements; restrictions on practice; and redress for wronged patients.

GOVERNMENT FINANCING

Societies differ as to how much medical care is considered adequate. In the United States, the President's Commission for the Study of Ethical Problems in Medicine concluded in 1983 that even though access to health care might not be properly considered a legal right, "society has a moral obligation to ensure that everyone has access to adequate care without being subject to excessive burdens." Programs for governmental payment of medical bills are an example of law used as an instrument to effect social policy. Changing the laws regarding financing rules may, in fact, have more of an impact on medical practice than any other legal interventions.

LICENSE REQUIREMENTS FOR PRACTICE

Legislative approaches to health-care licensing have been divided into three general categories by the legal scholar Jan Stepan: (1) exclusive or monopolistic systems, in which only the practice of modern, scientific medicine by professionals is lawful; (2) tolerant systems, in which only scientific medicine is officially sanctioned, although traditional medicine is tolerated; and (3) inclusive or integrated systems, in which traditional medicine is either recognized as a special part of the health system, or the integration of two or more systems of health care is officially promoted.

The exclusive systems. The exclusive system of licensing, which first emerged in Europe, involves granting licenses only to those who meet certain formal educational requirements; they are often required to pass a standardized examination and to demonstrate that they are of good moral character. The educational requirements usually apply to physicians, nurses, pharmacists, dentists, and other allied health professionals. Most medical schools in the world have similar courses of study, and a person who is graduated from almost any of them receives the M.D. degree (doctor of medicine) and is entitled to sit for a licensure examination. In Britain and many Commonwealth countries the graduate receives a bachelor of medicine and a bachelor of surgery or bachelor of chirurgery (M.B., B.S.; or M.B., Ch.B.); the M.D. is a higher degree that requires further study. The license to practice, called registration, is granted by the General Medical Council, which was established by the Medical Act of 1858.

Because of the similarities between educational and practice patterns, physicians often may be allowed to practice in countries other than those in which they are registered. In 1975 the Council of the European Economic Communities, for example, issued directives for the national recognition of primary and specialist medical qualifications so as to facilitate the free movement of doctors among the member states of the European Economic Community (EEC). Steps have been taken in most EEC countries to implement these directives. An Advisory Committee in Medical Training has been established by the EEC to assist in the formation of a common standard.

Legislatures originally adopted exclusive licensing in an effort to protect the public from untrained persons on the belief that the public was not qualified to judge medical skills and could easily be taken advantage of by unqualified practitioners. Licenses are generally granted for life and can be lost only by criminal conduct, gross incompetence, or mental disability. Virtually every country in the world, with the exceptions of China and Japan, initially followed the European model of exclusive licensing, and the type of health care this model imposed is based on Western science. What may have been reasonable for Europe and North America, however, makes little sense in rural Africa or South America, and it has become clear that more flexibility is needed to ensure better access to health care in many of the developing countries.

Exclusive approaches to medical care exist in almost every state in the United States and in France, Belgium, and most other European countries. In the United States, for example, it is a criminal offense for anyone to practice medicine without a license. The practice of medicine is usually defined to include diagnosis, treatment, prescription, and surgery. Physicians may lawfully practice in any branch of medicine and any of its subspecialties. Further education, training, and certification as a specialist is available through private, voluntary organizations. All other licensed health professionals, however, are strictly limited by statute to the areas in which they may practice. For example, dentists must only do work relating to dentistry.

Because the U.S. states have retained direct powers in health care, all licenses for health professionals are granted by the individual states. Licensing is regulated by administrative agencies, usually called state licensing boards, and licenses are valid only in the state issuing the license. Most states, however, grant a license by reciprocity upon request from a licensed physician, nurse, pharmacist, or dentist who is in good standing in another state. Licensing rules governing dentistry and pharmacy are parallel to medical licensure; the candidate must have been graduated from a professional school, have passed an examination, and be licensed by a state board set up for that purpose. Licensing

Registered nurses (R.N.'s) are required to have been graduated from a preparatory nursing program (with a bachelor's degree, associate degree, or diploma from a hospital-based program) and to have passed an examination. Licensed practical nurses (L.P.N.'s rather than R.N.'s), on the other hand, generally have to complete a one-year vocational program after graduating from high school. In almost all countries, national and local nursing associations are instrumental in proposing legislation for licensing or registration and in securing amendments to broaden the scope of nursing practices.

The tolerant systems. Tolerant systems operate in Britain, Germany, the Scandinavian countries, and some U.S. states, such as California. In Britain, for example, there is no formal legal monopoly of medicine. The protected status is that of registered medical practitioner. Under the Medical Act of 1978, persons who have fulfilled

Physicians' rights

statutory education and examination requirements are entitled to be registered. Registered physicians have certain exclusive rights, such as employment by the National Health Service, prescribing, issuing medical certificates, and holding appointments in public hospitals. It is an offense to imply falsely that one is registered, but it is not an offense to otherwise engage in healing. Osteopaths, chiropractors, and acupuncturists may practice in the private sector. The Dental Act of 1984, however, gives dentists a monopoly by making it an offense to practice dentistry when not registered as a dentist. Sweden is similar in that anyone may be a healer, but it is a crime to claim to be a physician when not so recognized by the state.

The inclusive and integrated systems. The inclusive and integrated systems are represented by countries such as India and China. In India the individual states regulate the practice of the health professions. A Medical Council maintains the Indian Medical Register, and any person on this register may practice anywhere in India. There are also state medical registers for the individual states, and people in these registers are also in the Indian Medical Register. Those who have obtained a degree from a university, usually M.B., B.S., or the qualification of licensed medical practitioner (L.M.P.) are entered in these registers. Qualifications from many foreign countries are also recognized for entry to the registers. Although it is now a crime to practice medicine without a license in India, this law was only enacted in 1970, and it does not apply to anyone who had practiced medicine without a license for at least five years before 1970.

China provides an example of an integrated system in which traditional Chinese doctors and Western-trained physicians practice side by side. The country has also developed a system in which certain persons receive a short, intensive training course and then provide primary health care in areas otherwise not served by health-care workers.

LEGAL RESTRICTIONS ON PRACTICE

Determination of death. The law generally supports customary medical practice and provides the medical profession with a great deal of autonomy. A dramatic example is the determination of death and the issuance of a death certificate. In almost every country of the world a physician declares a person dead and issues a death certificate after a determination of death is made in accordance with accepted medical standards. A question that recently appeared was whether physicians should continue to be given the authority to declare a person dead if the medical profession were to adopt whole brain death as an acceptable definition of death (instead of the past definition of irreversible cessation of respiration and heartbeat). A mechanical respirator can artificially maintain the respiration and circulation of a person whose functions would cease without such mechanical support. In the late 1960s the potentials of organ transplantation from such persons were becoming realized, and the seeming futility of devoting limited medical resources to maintaining circulation under such circumstances was of growing concern. Physicians began proposing that irreversible cessation of brain activity be used as an alternative definition of death.

Since that time, most Western countries have adopted this definition, by either continuing to permit physicians to declare death, passing a specific statute endorsing this definition, or issuing court opinions giving approval to physicians' declarations of death in such circumstances. The law, in short, has continued to defer to medical practice in the definition of death itself.

The countries that have not adopted brain death criteria have not done so primarily for cultural and religious reasons. For example, Japan has refused to adopt a brain-based definition of death in part because it would conflict with religious tenets that require the death of all major organs prior to a pronouncement of death. Accordingly, such medical techniques as heart transplantation cannot be performed in Japan (or in any country that does not accept a brain-death definition). Harvesting a beating heart from a person is considered in such countries to be homicide, even though brain activity has ceased and respiration is being maintained artificially.

Termination of pregnancy. Physicians have broad legal authority and discretion in other controversial areas as well. In countries like the United States, for example, where the law permits termination of pregnancy prior to fetal viability, it is for the physician, and not the state, to determine whether or not an individual fetus is viable (*i.e.*, capable of living independently of its mother); the determination must be made consistent with accepted medical criteria. When the Supreme Court declared that the decision to terminate a pregnancy was protected by the U.S. Constitution, it emphasized that the decision should be made by a woman and her physician. The law may restrict procedures like termination of pregnancy, sterilization, and even birth control to mature minors and adults; but it is generally left to the physician to determine if a patient is mature or competent to consent.

Sudden death. Unexpected deaths must be reported to public authorities so that a determination can be made as to whether the death was a homicide, a suicide, or an accident. It is up to an investigator, whether he is called a medical examiner or coroner, or has some other title, to make a preliminary finding and then to refer the case to the police or prosecuting authorities if criminal activity is suspected. In most Western countries this person has either legal training, medical training, or both. In the United States, some jurisdictions use an elected coroner (who may or may not have medical training); however, the trend is toward a medical examiner system in which a physician is appointed to the post. Coroners in London are qualified both in medicine and in law. The principal evidence received by the coroner is the report of the autopsy carried out on the body of the deceased.

Public reporting. Physicians may also be expected to report certain patients or occurrences to public authorities. For example, some communicable diseases are required to be reported to public health officials. Suspected child abuse and gunshot wounds may have to be reported to an authority (such as the child welfare authority or the police). Public reporting tends to put the physician in the position of being an agent of the state rather than of his patient, making mandatory reporting an uncomfortable duty. It is not surprising, therefore, that the incidence of public reporting is often thought to be lower than may be warranted.

Effect of public reporting

In extreme cases, physicians may also have a duty to warn specific individuals who may be at serious or mortal risk from their patients. For example, the California Supreme Court decreed that a psychologist had a "duty to warn" a person whom his patient had threatened to kill, if the psychologist believed "or should have believed" the threat to be real. In that particular case the patient, a graduate student, left the psychologist's care and murdered his former girlfriend, an action that the psychologist believed was so likely that he had sought unsuccessfully to have his patient involuntarily committed.

LEGAL REDRESS

When patients are injured by medical negligence the remedies they can pursue depend upon the country's legal system. In the United States, for example, lawsuits against physicians for negligent injury are not considered unusual.

Malpractice, or professional negligence, is the failure of a health-care provider (for example, a physician, dentist, nurse, or pharmacist) to exercise the ordinary care and skill a reasonably prudent, qualified person would exercise under the same or similar circumstances. The practitioner does not guarantee the outcome but must use diligence and ordinary skill in the treatment of a patient.

A valid malpractice claim must have four elements: duty, breach, damages, and causation. The practitioner must be shown to have a relationship to the patient (which establishes a duty to exercise ordinary care); must have breached that duty (as measured by the applicable standard of care); and through the breach must have caused the patient physical and monetary damages.

The central concern for physicians is usually to establish the standard of care through expert testimony, which may simply be the testimony of another qualified physician. Such testimony is necessary because the standard of med-

ical practice is not something a lay jury is familiar with. Expert witnesses may themselves rely on the standards that have been set down by one or more of the medical speciality organizations, such as the American College of Obstetricians and Gynecologists. These medical speciality organizations provide certification to physicians who have fulfilled postgraduate training and practice requirements in the speciality. They maintain the standards necessary to practice in the specialities, and they provide reasonable assurance to patients that these standards will be upheld. Nonconformance with such standards by a specialist is evidence of negligence, although it is not conclusively negligence (the practitioner may have a valid excuse for not following custom, such as an emergency situation or lack of equipment). Conformance with the standards is evidence of due care, but it is not conclusive because other factors may have caused the physician's action to be imprudent under the circumstances.

If a practitioner consistently performs below the profession's standard of care (*i.e.*, the practitioner is a negligent physician who does not actually harm anyone) the remedy is not a malpractice action but a complaint to the licensing or registration authority to have the individual disciplined. Disciplinary action by public licensing authorities, however, is unusual.

Functions of malpractice

Medical malpractice actions have three basic functions: quality control, compensation for harm, and emotional vindication, all of which are achieved to varying degrees. Quality control is probably best achieved, since the standard of care is set by physicians themselves and enforced by patients and juries. Compensation for harm, on the other hand, is skewed toward major injuries. Attorneys in the United States, for example, represent malpractice cases on a contingency fee basis—*i.e.*, they are paid a proportion (usually 20–40 percent) of the total amount awarded to the plaintiff. Patients who suffer less severe injuries may have little redress for compensation. In countries that have a system of national health insurance, compensation for harm may not be a major issue (since all medical bills are paid regardless of cause). And countries with comprehensive social services for all citizens, like Sweden and New Zealand, have effectively developed "no fault" compensation systems. But in the United States, where more than 35,000,000 people do not have any form of health-care insurance, lack of coverage can transform a medically induced injury into a financial catastrophe.

Emotional vindication is a measure of the consumer's ability to make a complaint as well as to get a satisfactory response. A comparison in consumer complaints between the United States and Britain shows significant differences. In 1981 an estimated 700 writs for medical malpractice were issued in Britain. In 1983 about 42,000 claims were filed in the United States. These figures yield a per capita difference (even when the difference in years and between claims and writs is considered) that shows that Americans file claims against physicians more than 10 times as often as their British counterparts. The law professor Frances Miller has noted that many cultural and practical reasons serve to explain this difference, including different legal systems and rules, access to attorneys and courts, the method of paying for medical expenses, the special status of the National Health Service in Britain, and the existence of alternative complaint procedures.

Patients' rights

In addition to granting patients means for the effective redress for negligent injury (which increases the cost of malpractice insurance for physicians—and thus the cost of medical care), malpractice litigation has also promoted what have come to be called patients' rights.

Fundamental premises

Patients' rights are based upon two fundamental premises: (1) the patient has certain interests, many of which may be properly described as rights, that are not automatically forfeited by entering into a relationship with a doctor or health-care facility; and (2) doctors and health-care facilities may fail to recognize the existence of these interests and rights, fail to provide for their protection or assertion, and frequently limit their exercise without recourse.

Perhaps the most important development in patient rights has been that in the United States regarding the doctrine of informed consent. This doctrine requires physicians to share certain information with patients before asking for their consent to treatment. The doctrine is particularly applicable to the use of surgery, drugs, and invasive diagnostic procedures that carry risks. It requires the physician to describe the procedure or treatment recommended and to list its major risks, benefits, alternatives, and likely prospect for recuperation. The purpose is to promote self-determination by patients on the theory that it is the patient who has the most at stake in treatment and who relies largely on the physician for such information. British courts have rejected this formulation on the basis that the average British citizen does not want such information, and British physicians do not generally provide it unless requested.

In 1972 the American Hospital Association adopted a patient bill of rights based on the premise that "[the] traditional physician-patient relationship takes on a new dimension when care is rendered within an organizational structure . . . the institution itself also has a responsibility to the patient." The text of the American Hospital Association bill of patient rights calls for the rights of the patient to respectful care, complete medical information, information necessary for informed consent, refusal of treatment, privacy, confidentiality, response to requests for service, information on other institutions involved in the patient's care, refusal of participation in research projects, continuity of care, examination and explanation of financial charges, and knowledge of hospital regulations.

In the mid-1970s the Parliamentary Assembly of the Council of Europe submitted a draft recommendation to its member nations suggesting that all necessary action be taken to ensure that the sick can receive relief from their suffering and that patients be adequately prepared for death. They further recommended that commissions be established to study the issue of euthanasia and that physicians acknowledge that the sick have a right to full information, if requested, on their illness and the proposed treatment. The council listed the following basic rights for the humane and dignified treatment of patients: the right to freedom, to personal dignity and integrity, to information, to proper care, and to not suffer.

No one bill of rights is suitable for every health care institution, and specialty hospitals, such as maternity and pediatric hospitals, may require different approaches. Among the basic rights of a patient should be the right to clear communication: accurate information concerning possible medical care and procedures; informed participation in all decisions involving the patient's health-care program; and a clear, concise explanation of all proposed procedures, including possible risks, side effects, and problems related to recuperation.

Proposed basic rights

Patients also should have rights regarding quality of care: a right to an accurate evaluation of their condition and prognosis without treatment; knowledge of the identity and professional status of those providing services; information contained in their medical record; access to consultant specialists; and refusal of treatment.

The patient should have basic human rights: the right to privacy of both person and information; of access to people outside the health-care facility; and to leave the health-care facility regardless of his condition.

The goals of such a system are to protect patients, especially those at a disadvantage within the health-care system (*e.g.*, the young, the illiterate, the uncommunicative, and those without relatives); to make available to those who seek it the opportunity to participate actively with the physician as a partner in a personal health-care program; and to put into proper perspective medical technology and pharmaceutical advances.

Until the 1960s law and medicine met only in the courtroom, and then usually only in cases involving pathology or psychiatry. Since then, however, civil litigation, public financing, and ethical issues have grown, at least partially as a result of the incredible successes of medicine. These successes have increased public expectations and increased the cost of medicine; they also have made decisions about

terminating care more ambiguous. Enhancing patients' rights is one modern concern on which both medical and legal practitioners agree. (G.J.A.)

Melbourne

Although the central city is the home of fewer than 100,000 people, Melbourne is the core of an extensive metropolitan area and is the world's most southerly urban area with a population of more than 1,000,000. It is situated on the southeastern coast of Australia, at the head of Port Phillip Bay, and is the capital of the state of Victoria. In Australia its metropolitan area is second only to Sydney's in population, and there is a good-natured rivalry between the two cities, to which geography and history have bequeathed diverse characteristics. Though Melbourne's flat site has led to the regular development of a rectangular pattern of streets, the city has many beautiful parks, and the person with an eye for architectural detail and history can find much that is varied and attractive. Melbourne has a reputation for conservatism and financial soundness—attributes that have contributed to its growth and are revealed by the burgeoning skyline of the central city and the rapidly expanding eastern suburbs.

This article is divided into the following sections:

Physical and human geography

THE LANDSCAPE

The Melbourne Statistical Division, which includes all areas in close economic and social contact with the central city, covers 5,455 square miles (8,784 square kilometres). The continuous, densely settled metropolis, where a vast majority of the residents live, is less than half the size of the larger division, and the city proper is only 22.7 square miles (36.5 square kilometres).

The city site. Metropolitan Melbourne is situated at the northern end of Port Phillip Bay, 30 nautical miles (55 kilometres) from the bay's narrow entrance. Most of the flat terrain is less than 390 feet (120 metres) above sea level. The expansion of Melbourne from its origins at the mouth of the Yarra River to its present shape displays a strong correlation with the geology and drainage of the land. West of the original city site, basalt flows during the Tertiary Period filled the existing valleys and left flat, uniform plains. The eastern region, however, consists of undulating and dissected beds of sandstones, shales, and conglomerates laid down in the Silurian and Devonian periods. The thicker soils of the eastern region, together with its higher annual rainfall, supported a much denser cover of trees than on the basalt plains. Not surprisingly, the development of Melbourne has been mainly eastward into the broad reaches of land between Darebin Creek, the Plenty and Yarra rivers, and Koonung and Gardiners creeks. In a strikingly asymmetrical fashion, Melbourne's urban development presently lines the entire eastern shore of Port Phillip Bay, from the mouth of the Yarra River to Point Nepean, 60 miles (97 kilometres) distant, while corresponding development on the west coast of the bay extends for only 10 miles.

Asymmetrical urban growth

Climate. Melbourne's weather results from the eastward flow of high-pressure cells separated by low-pressure troughs. These patterns follow a course that passes south of the continent in summer and over northern Victoria in winter. The annual rainfall of 26 inches (657 millimetres) is fairly evenly distributed throughout the year, with October usually the wettest month and January the driest. Temperatures are moderate, only rarely falling below freezing; average daily maximum temperatures vary from 55° F (13° C) in July to 79° F (26° C) in January. Winds associated with the eastward passage of weather systems ensure that Melbourne is spared the serious air pollution of some other large cities.

The city layout. The area of original settlement in Melbourne, which today forms its financial, legal, administrative, and ecclesiastical heart, was laid out in a rectangular pattern that has not changed. The area has a frontage along the Yarra River. Within this core are the major suburban and interstate railway stations, Victoria's Houses of Parliament, the Anglican and Roman Catholic cathedrals, arts and entertainment venues, museums, the Law Courts, the State Library, and many financial institutions, including the Melbourne Stock Exchange and the headquarters of major banks. Central to this area are two major destinations, Bourke and Swanston streets, which have been transformed into pedestrian malls, closed to automobile traffic. Most of the city's buildings are modern, but the Town Hall, the Law Courts, and the Exhibition Building provide excellent examples of 19th-century official architecture. The city is divided into 14 precincts, sectors identified by ethnic concentration, commercial clusters, or attractions.

The earliest suburbs—Carlton, Collingwood, Richmond, Prahran, St. Kilda, and Brighton—also have a generally rectangular pattern of streets. Row houses, often with verandas decorated with iron lacework, were common features in the suburbs close to the city's centre; and in parts of Carlton and South Melbourne some of these traditional terraces have been preserved.

THE PEOPLE

Patterns of immigration. The first official census of Melbourne, in 1836, numbered 177 persons, of whom 35 were

females. In the 1850s the gold rush in nearby areas of Victoria sparked the city's first major period of immigration. Newcomers came principally from other Australian colonies and Britain. By the 1920s Melbourne had become the home of more than half the residents of Victoria, and toward the end of World War II it reached a population of 1,000,000. This trend continued throughout the 20th century. By 2000 the Melbourne metropolitan area comprised nearly three-fourths of Victoria's population.

The second great wave of immigration came in the 1950s, when the Australian government pursued a deliberate policy of encouraging migration from Europe to provide workers for Australia's developing industries. The government provided assistance with travel costs and helped the immigrants to settle in Australia, learn English if necessary, and find employment. At first migrants were drawn mainly from the Baltic states and eastern Europe, many of these people being war refugees. Then larger numbers began coming from the United Kingdom and Ireland. Immigration agreements were signed with the Dutch, Maltese, West German, Italian, Greek, and Austrian governments. These programs sowed the seeds of Melbourne's present multicultural character. Italians, Greeks, and Yugoslavs formed the largest numbers of non-English-speaking migrants, and by the mid-1970s one-fifth of the city's population regularly spoke a language other than English. Immigration from Southeast Asia, in particular refugees from Vietnam and Cambodia, increased during the early 1980s.

Diverse ethnic population

Move to the suburbs. By 1966 the population of the Melbourne area had exceeded 2,000,000, and the city limits were rapidly being pushed eastward. The migrants from southern Europe were at first concentrated in the older industrial suburbs, where they found lower rents and nearby job opportunities. In those areas, too, support was available from earlier immigrants and the associations they had established. As these people prospered, however, they embraced the Australian dream of owning a home on a quarter-acre plot and began to move to the outer suburbs.

In the 1940s about 90 percent of Melbourne's residents lived within 10 miles of the central business district. By the 1980s this proportion had fallen to less than 50 percent, and the outer suburban areas had grown correspondingly. Although some western sections can be typified as working-class districts, on the whole Melbourne's suburbs represent a fairly even mixture of social classes and occupations. By the end of the 20th century, however, the trend began to reverse itself. The central city became increasingly residential as many aging buildings were rehabilitated and repurposed as housing. In addition, by 2000 the area's population had surpassed the 3,000,000 mark.

THE ECONOMY

Industry and trade. That Melbourne dominates the economic life of Victoria is not surprising—the city contains the bulk of the state's population. It is Victoria's financial centre and seat of government and is at the hub of the communications network linking the state to the rest of Australia and the world.

The city's original core offers the most employment, but employment is growing at a faster rate in the outer suburbs. The central city mainly holds service activities such as banking, insurance, retailing, entertainment, public accommodation, and railway transportation. Surrounding this core is an incomplete ring of inner industrial suburbs, where the first clothing and metal factories were established in the 19th century. In the outer suburbs, particularly to the east, small manufacturing areas began to develop after World War II, when these suburbs could offer large areas of inexpensive land, few problems of traffic congestion, and an increasing population.

In the 1990s an ambitious project was launched to develop Docklands, a 500-acre (200-hectare) site of crumbling industrial and port facilities, into a multiuse complex featuring high-technology businesses, parks and public spaces, restaurants, a theme park, and apartment buildings and other housing. Docklands was expected to become home for 15,000 people and a workplace for 20,000. The first major facility, Colonial Stadium, a sports and entertainment venue, opened in 2000.

Melbourne's most important industries, in terms of numbers employed, are metal processing, including the manufacture of transportation equipment, and engineering. Other major industries include textile and clothing manufacture; food processing; papermaking and printing; and the manufacture of chemicals, furniture, and building materials. Melbourne is also one of Australia's leaders in the manufacture of computers and is developing as a centre for biomedicine and biotechnology.

The port of Melbourne occupies an area of level excavated land at the mouth of the Yarra River, southwest of the central business district. It is the nation's largest general-cargo port. The chief products handled are foodstuffs, crude oil and petroleum products, chemicals, and iron and steel.

The commercial port

Beginning in the 1960s, large regional shopping centres sprang up throughout Melbourne's outer suburbs, and the central city lost its dominant retail function. Nonetheless, major department stores and fashionable shops still exert a considerable pull on both residents and visitors.

Transportation. Melbourne is well served by an integrated public system of trains, buses, and tramcars, the latter a signature sight in the city. A network of national highways link Melbourne with adjoining states, and a system of freeways was greatly upgraded in the 1990s, including the creation of the Western Ring Road as a bypass route. The City Link project joined three major freeways with a bridge, tunnels, highway extensions, and interchanges to facilitate traffic movement. An underground rail loop serves the central business district. Melbourne's international and domestic airport is located at Tullamarine, 14 miles northwest of the city's centre.

ADMINISTRATION AND SOCIAL CONDITIONS

Government. The Victoria state government has the ultimate responsibility for Melbourne's major planning decisions and for providing its principal health, educational, and transport services. Local government in the Melbourne Statistical Division is provided by more than 30 entities. Councillors, led by a lord mayor, are elected under a system of compulsory voting conducted by mail. Councillors receive a stipend and represent the city at large. The councils pass local ordinances and control a number of services connected with building regulations, community welfare, garbage collection, and vehicle parking. Revenue for these purposes is raised by property taxes (rates).

Health and education. Since the system of free public hospitals was started in 1846, it has grown to encompass numerous special facilities, which deal with either particular ailments or categories of patients, as well as general hospitals. There are, in addition, many private hospitals.

The University of Melbourne, one of the oldest in Australia, was established in 1853 (though the first students were admitted in 1855); Monash and La Trobe universities were established in the 1960s, and Deakin University, established in 1974, maintains three campuses. Melbourne also has colleges of advanced education that offer degrees or diplomas in a variety of technical and academic subjects.

CULTURAL LIFE

Arts. Melbourne's already rich cultural life was greatly enhanced during the period between 1968 and 1984, when the Victorian Arts Centre was created on the south bank of the Yarra River close to the city's centre. It encompasses the National Gallery of Victoria, the Melbourne Concert Hall, and several theatres, among other facilities for the arts.

The arts centre

The National Gallery was originally opened in 1861 and moved to its present site in the arts centre in 1968. It houses several outstanding collections including, most notably, Australian art ranging from the colonial period to modern times; European art, with 18th-century works particularly well represented; and decorative arts.

The Melbourne Concert Hall seats 2,600. Its patrons appreciate not only the technical brilliance of the acoustic en-

gincering but also the hall's superb decorations in colours derived from the gemstone and mining industry, which makes the hall appear to have been carved out of a hillside.

Performance spaces of the arts centre include the State Theatre, the Playhouse, the George Fairfax Studio, and the Black Box, providing facilities for opera, ballet, musical theatre, drama, stand-up comedy, cabaret, and a variety of music. The Sidney Myer Music Bowl, in King's Domain Gardens opposite the arts centre, is an outdoor venue seating 13,000. Yearly seasons of opera, ballet, and concert music include performances by international artists. The Melbourne Symphony Orchestra was formed in 1949 and has toured North America, Japan, and New Zealand, as well as major Australian cities.

Recreation. Automobile license plates in Victoria carry the identification "Victoria—Garden State." Melbourne is worthy as the capital of a garden state, with more than one-fourth of its inner-city area consisting of public parks and reserves. These spaces were set aside in the mid-19th century, at a time when many civic leaders in other cities were concerned with commercial development rather than with the quality of life. Extensive tracts have also been allotted as parklands in the newer outer suburbs. The most famous park in Melbourne is the Royal Botanic Gardens (RBG). This area of 89 acres was established in 1846 and today contains lakes, lawns, and thousands of named trees and shrubs. The associated National Herbarium of Victoria, which houses a collection of some 1,200,000 pressed plant specimens, is internationally recognized and used by scholars. The RBG also maintains a separate 200-acre facility at Cranbourne, about 30 miles southeast of central Melbourne.

Melbourne has hundreds of sports fields, tennis courts, swimming pools, and golf courses for active sports participants. Spectators find good accommodations at the Melbourne Cricket Ground, which holds 100,000 and is used for both cricket and Australian Rules football, and at the Flemington Racecourse, where the valuable Melbourne Cup race is held every November. Melbourne hosted the 1956 Summer Olympic Games. New sports facilities, including a large tennis stadium near the Melbourne Cricket Ground, have been added since the Olympics. Sailing and fishing on Port Phillip Bay and surfing on the ocean beaches are also popular, and the winter ski slopes around Mount Buller are within easy reach.

History

EARLY SETTLEMENT

Port Phillip Bay was discovered by Europeans in 1802, when captains John Murray and Matthew Flinders visited the bay within a few months of each other. This area was then part of the colony of New South Wales, and the colony's governor, Philip Gidley King, instructed the surveyor-general, Charles Grimes, to examine the shores of the bay with a view to identifying sites for future settlement. In 1803 Grimes and his party discovered the Yarra River and traveled along its lower course. Unlike some members of the party, Grimes was not enthusiastic about the Yarra River as a potential settlement. Later in the same year Captain David Collins arrived with a contingent of soldiers and convicts and settled near Sorrento, just inside the entrance to the bay on the east coast. Within a few months, however, he decided that the location was unsuitable and moved his group to Tasmania.

Exploration of Port Phillip Bay

Permanent settlement was delayed until 1835, when a pioneer settler and entrepreneur, John Batman, negotiated a treaty with the Aboriginal elders for the purchase of 500,000 acres at the head of Port Phillip Bay. The price was 40 blankets, 30 axes, 100 knives, 50 scissors, 30 mirrors, 200 handkerchiefs, 100 pounds of flour, and six shirts. Batman and his heirs were bound by the treaty to provide an annual "rent of tribute" of similar items.

A few days after the treaty was signed, Batman left, and two months later a party led by another pioneer, John Fawkner, settled on the banks of the Yarra River. There has been much debate about whether Batman or Fawkner should be regarded as the founder of Melbourne. Both seem to have an equal claim, but if the term is interpreted to include expansion and consolidation of the settlement, then the honour must go to Fawkner. Within four years of signing his treaty, which had been disallowed by the Governor of New South Wales, Batman died, at age 38; his financial affairs were in disarray, and prolonged litigation over his will destroyed the estate he had created. Fawkner lived to the age of 76. He died in Melbourne in 1869 after a rewarding career in which he established hotels, a newspaper, and a bookselling business, acquired large areas of land, and held a seat on the Legislative Council for 18 years.

Melbourne is distinguished from the other Australian state capitals in that it was founded unofficially, by individual enterprise. Once Batman, Fawkner, and others had established the settlement in 1835, the government in Sydney had to recognize the fact. In 1836 the first administrator of the Port Phillip District arrived, and in 1837 the new settlement was given its present name honouring the British prime minister, William Lamb, 2nd Viscount Melbourne (of Kilmore). Melbourne became a town in 1842 and a city in 1847, but its first main surge in growth came in the early 1850s following the discovery of gold near Bendigo and Ballarat less than 100 miles away. In three years the population of Melbourne increased fourfold to 80,000.

The gold rush

GROWTH OF THE CITY

Melbourne capitalized on its central position within Victoria and its port facilities to capture most of the region's trade. Between 1856 and 1873, railways were built to Geelong, Ballarat, Bendigo, Echuca, and Wodonga, and in 1883 a link with the New South Wales rail system was established at Albury. In 1877 the Melbourne Harbour Trust was created, and the Coode Canal was cut in the soft alluvial sediments of the lower Yarra River to provide a more direct course free from silting problems.

During the 1870s manufacturing flourished under the protection of a high tariff, and progress in most spheres continued until 1889, when a financial crisis and the collapse of many firms lowered public confidence. The following decade witnessed a severe economic depression that began with a maritime strike and the failure of a number of banks and was sealed by seven years of drought from 1895 to 1902. In the decade before 1891 the population of Melbourne had increased by 200,000; in the following decade it rose by only 6,000.

In the early years of the 20th century, confidence gradually revived. Australia became a commonwealth, and Melbourne served as its federal capital until 1927, when Canberra was established. World Wars I and II encouraged the growth of manufacturing, and after 1945 European immigrants began to arrive in significant numbers.

After 1971 Melbourne's rate of growth slackened as immigration declined, and economic conditions worsened through the 1970s and early '80s. Nevertheless, during this period of slower population growth a number of major changes took place. The appearance of the inner city was transformed by the replacement of old buildings with multistory office structures and hotels. The system of arterial roads was improved dramatically. Several important suburban economic areas emerged, reducing the retail and industrial importance of the city's centre. And the cultural life of the city was immeasurably enlivened by the completion of the Victorian Arts Centre. The revitalization of central Melbourne continued after 1990 as the residential population grew and the massive Docklands development project began to transform the long-neglected waterfront area into a spectacular urban showplace.

Memory

That experiences influence subsequent behaviour is evidence of an obvious but nevertheless remarkable activity called remembering. Learning could not occur without the function popularly named memory. Practice results in a cumulative effect on memory leading to skillful performance on the tuba, to recitation of a poem, and even to reading and understanding these words. So-called intelligent behaviour demands memory, remembering being prerequisite to reasoning. The ability to solve any problem or even to recognize that a problem exists depends on memory. Typically, the decision to cross a street is based on remembering numerous earlier experiences.

Practice (or review) tends to build and maintain memory for a task or for any learned material. Over a period of no practice what has been learned tends to be forgotten; and the adaptive consequences may not seem obvious. Yet, dramatic instances of sudden forgetting (as in amnesia) can be seen to be adaptive. In this sense, the ability to forget can be interpreted to have survived through a process of natural selection in animals. Indeed, when one's memory of an emotionally painful experience leads to severe anxiety, forgetting may produce relief. Nevertheless, an evolutionary interpretation might make it difficult to understand how the commonly gradual process of forgetting survived natural selection.

In speculating about the evolution of memory, it is helpful to consider what would happen if memories failed to fade. Forgetting clearly aids orientation in time; since old memories weaken and the new tend to be vivid, clues are provided for inferring duration. Without forgetting, adaptive ability would suffer; for example, learned behaviour that might have been correct a decade ago may no longer be. Cases are recorded of people who (by ordinary standards) forgot so little that their everyday activities were full of confusion. Thus, forgetting seems to serve the survival of the individual and the species.

Another line of speculation posits a memory storage system of limited capacity that provides adaptive flexibility specifically through forgetting. In this view, continual adjustments are made between learning or memory storage (input) and forgetting (output). Indeed, there is evidence that the rate at which individuals forget is directly related to how much they have learned. Such data offer gross support of contemporary models of memory that assume an input-output balance.

Whatever its origins, forgetting has attracted considerable investigative attention. Much of this research has been aimed at discovering those factors that change the rate of forgetting. Efforts are made to study how information may be stored; that is, to discover the ways in which it may be encoded. Remembered experiences may be said to consist of encoded collections of interacting information; and interaction seems to be a prime factor in forgetting.

This article treats the phenomena and functions of normal memory; it also discusses the variety of disorders that affect the memory. The article is divided into the following sections:

The nature of memory: retention and forgetting

Psychologists of the modern era, from their earliest speculations about remembering to the formulation of most of their latest experimentally based views, commonly have assumed that the critical problems are concerned with the physiological mechanisms by which events and experiences can be retained so that they can be mentally reproduced, either in their original mode or with the assistance of signs and symbols that are regarded as equivalent to that mode. Memory is thus usually considered to function perfectly in proportion to its literal accuracy of reduplication. Investigators have generally supposed that anything that influences the behaviour of an organism endowed with a central nervous system leaves—somewhere in that system— a "trace" or group of traces. So long as these traces last they can, in theory, be restimulated and the event or experience that established them will be remembered. The experimental psychology of remembering—all modern experts claim to base their conclusions upon experimental evidence—endeavours to discover methods for identifying the necessary and sufficient conditions for the persistence and length of persistence of traces and for their restimulation.

MEASURING RETENTION

Standard sentences, prose passages, and poems have been used to control input in studies of retention; but discrete verbal units (such as words or sets of letters) are most frequently employed. The letters usually comprise lists of consonant syllables (three consonants; *e.g.*, RQK) or so-called nonsense syllables (consonant-vowel-consonant; *e.g.*, ROK). The order in which verbal units are to be learned and to be recited may be left to the subject (free recall). A schoolchild who can recite the names of all African countries probably has learned such a free-recall task. Units also can be presented serially (in a constant order), the subject being asked to recite them in that order; reciting the alphabet in the usual way represents such serial learning.

Free recall, serial learning, paired-associate tasks

Pairs of words may be offered; in such paired-associate tasks the subject eventually is asked to produce the missing member of each pair when only one word is shown. This is akin to learning English equivalents for words from another language.

For these and similar tasks investigators commonly permit subjects enough practice trials to reach some preselected criterion or level of performance. This level effectively defines an immediate retention score against which later forgetting may be measured. Subsequent tests of retention are then made to investigate the rate at which forgetting proceeds. This rate tends to vary with the methods used, basically those of recall, recognition, or relearning.

Recall. Subjects may be asked to reproduce (recall) previously learned data in any order or in the original order in which they were learned.

In a free-recall test the instructions might be: "Yesterday you learned a list of words; please write as many of those words as you possibly can as they occur to you." For the paired-associate task the subject may be told: "Yesterday you learned some pairs of words; I will show you one word from each pair and you try to give the other." He may be paced, being limited to a few seconds to produce each word; or he may be unpaced, being given no rigidly specified limits.

If retention of any kind is to be measured over different periods (*e.g.*, an hour, a day, a week) a separate group of individuals should be used for each period. The reason is that the very act of remembering constitutes practice that keeps memory lively, tending to give misleading underestimates of the rate of forgetting if the same subjects are tested over successive intervals.

Recognition. The subject's task is simpler in tests of recognition, since reproduction or retrieval (as in recall) is not required. The subject simply is asked to remember previously presented information when it is offered to him again. For example, he may be given a list of words for study; on the subsequent test of retention these are mingled with additional words, the subject being asked to identify (recognize) the original words. Apparently the recognition test stresses ability to choose between "old" (studied) data and "new" words, although this need not mean that choices are based only on temporal discrimination (awareness of time distinctions).

In an alternative variety of recognition test, each word studied might be paired with a new one, the task being to choose the old member of each pair. Or, the test words might be presented one at a time for identification as old or new. Sometimes learning and testing are combined: a very long list of words may be presented one at a time, some being repeated; the task is to recognize the repeats.

Some recognition tests stress memory of the order of presentation. The subject learns a serial list (reciting in a prescribed order); the list then is scrambled, and he is tested on his ability to rearrange it appropriately. Order may be based on how units are arranged in space (*e.g.*, printed on a page) or on their numerical position in a series or on associative information. Thus, if a paired-associate list has been learned, the test may consist of the unmatched presentation of all units with a request to pair them properly. This sort of recognition seems to emphasize associative attributes. If some elements on the test were not presented originally, the temporal attribute also may be involved.

Relearning. The number of successive trials a subject takes to reach a specified level of proficiency may be compared with the number of trials he later needs to attain the same level. This yields a measure of retention by what is called the relearning method. The fewer trials needed to reach the original level of mastery, the better the subject seems to remember. The relearning measure sometimes is expressed as a so-called savings score. If 10 trials initially were required, and five relearning trials later produce the same level of proficiency, then five trials have been saved; the savings score is 50 percent (that is, 50 percent of the original 10 trials). The more forgetting, the lower the savings score.

Although it may seem paradoxical, relearning methods can yield both sensitive and insensitive measures of forgetting. Tasks have been devised that produce wide differences in recall but for which no differences in relearning are observed. (Some theorists attribute this to a form of heavy interference among learned data that has only momentary influence on retention.) Six months or a year after initial learning, some tests may give zero recall scores but can show savings in relearning.

Short-term and long-term memory

When relatively long retention intervals (usually hours or days) are used, the methods are said to involve long-term memory. In a sense, methods for studying short-term memory are miniaturized versions of these. A list may be as short as one item, level of proficiency is very low, and retention intervals are in seconds (or minutes at most).

For example, the subject may be shown a single nonsense syllable for a few seconds' study. Next he is given a simple task (such as counting backward) to occupy him for a half minute so that he cannot rehearse, and then is asked to recall the syllable. Forgetting is observed to occur over such short intervals, tending to be greater when length of interval increases, as in long-term memory. The same procedure can be used with a single paired-associate item or with a short list of four or five pairs. In a short-term counterpart of serial learning, a string of about eight single-digit numbers or letters is presented very rapidly (say, two per second), and the subjects are asked to recall them in the order in which they were presented. Recognition tests also can be adapted for measuring short-term retention. When only one presentation is used for learning, however, relearning measures are obviously unfeasible.

TIME-DEPENDENT ASPECTS OF RETENTION; STORAGE AND RETRIEVAL

Some workers theorize a distinct short-term memory system of sharply limited capacity that can retain information perhaps only a few seconds and a long-term system of relatively unlimited capacity and retention.

Among typical people, short-term function seems limited to about seven separate units (*e.g.*, seven random letters or unrelated common words). Thus, one may consult a telephone directory and forget the number before dialing is completed. Information seems to enter long-term storage by such processing as rehearsal and encoding, as if short-term retention is a way station between incoming information and more enduring memory.

Other theorists do not distinguish short- and long-term systems as inferred from observed differences in capacity and retention. Positing only one storage system, they attribute short-term phenomena to very low levels of learning. Those who postulate distinct systems point to the results of injury to a specific brain region (the hippocampus): (1) information stored prior to hippocampal damage seems to be retained; (2) sufferers seem incapable of new long-term storage; (3) the short-term functions appear to be unimpaired and subjects perform as well as ever in tests of immediate memory (*e.g.*, for a set of random numbers). It is as if new information no longer can be transferred from some sort of short-term system to relatively enduring storage.

Neurological evidence

Other data that bear on the controversy among theorists come from studies of people without known brain injury. When one has just seen a new list of words one at a time, the initial words in the list tend to be recalled best (primacy effects), those at the end next best (recency effects), while items from the middle are least likely to be recalled. This is quite consistently found as long as recall begins immediately following presentation of the last word. If, however, a short interval follows, during which the subject is otherwise occupied to prevent rehearsal, the recency effect may completely disappear: words at the end are no better recalled than those in the middle. Primacy effects are essentially undisturbed, while a delay as short as perhaps 15 seconds is enough to abolish the recency phenomenon. Although some suggest that recency effects depend on a separate short-term memory system and that primacy effects are mediated by a long-term system, a single memory function also may be invoked to accommodate the findings. Nevertheless, interest is growing in multisystem theories on the grounds that they enhance appreciation of the processes involved in establishing relatively enduring memory.

Investigators concerned with physiological bases for memory seek a kind of neurochemical code with enough stability physically to produce a structural change or memory trace (engram) in the nervous system; mechanisms for decoding and retrieval also are sought. Efforts at the strict behavioral level similarly are directed toward describing encoding, decoding, and retrieval mechanisms as well as the content of the stored information.

One way to characterize a memory (or memory trace) is to identify the information it encodes. A learner may encode far more information than is apparent in the task as presented. For example, if a subject is shown three words for a few seconds and (after 30 seconds of diversion from rehearsal) is asked to recall and then another triad of words is given under the same procedure, then

another, and so on, then if all triads share some common element (*e.g.*, all are animal names), poorer and poorer recall is observed on successive trials. Such findings may be explained by assuming that the learner encodes this animal category as part of his memory for each word. Initially, the common code might be expected to aid recall by sharply delimiting the word population. Successive triads, however, should tend to be encoded in increasingly similar ways, blurring their unique characteristics for the subject. An additional step provides critical supporting evidence for such an interpretation. If a final triad of vegetable names is unexpectedly presented, recall recovers dramatically. The subject tends to reproduce the vegetable names much better than he does those of the last animal triad; recall is about as efficient as it was for the first three animal names. This particular shift clearly seems to provide escape from earlier confusion or blurring, and it may be inferred that a common conceptual characteristic was encoded for each animal name.

Encoding mechanisms

Any characteristic or attribute of a word may be investigated in this way to infer whether it is incorporated in memory. When recall does not recover it would seem that the manipulated characteristic has little or no representation in memory. For example, grammatical class typically does not appear to be encoded; decrement in recall produced after a series of triads consisting of verbs tends to continue when a shift is made to three adjectives. Such an experiment does not indicate what common encoding characteristic might be responsible for the decrement, suggesting only that it is not grammatical class.

Encoding mechanisms also may be inferred from tests of recognition. For example, subjects study a long list of words, being informed of a multiple-choice memory test to follow. Each word studied is made part of a test item that includes other carefully chosen new words (distractors). Distractors are selected to represent different types of encoding the investigator suspects may have occurred in learning. If the word presented for study is chosen by the subject, little can be inferred about the nature of the encoding. Any errors, however, can be most suggestive. Thus, if the word presented for study was TABLE, the multiple-choice item might be TABLE, CHAIR, ABLE, FURNITURE, PENCIL. If CHAIR is incorrectly selected, it may be suspected that this associatively related word occurred to the subject implicitly during learning and became so well encoded that the subject later could not determine whether it or TABLE had been presented. If the wrong choice is ABLE, acoustical resemblance to TABLE may have contributed to the confusion. If FURNITURE is erroneously chosen, perhaps conceptual category was prominent in the encoding.

Since it is not related in any obvious way to TABLE, the word PENCIL may be intended as a control, unlikely to be a part of the memory for TABLE. If this is the case, subjects should be more likely to select distractor words other than PENCIL (if indeed they have been encoded along with TABLE).

Although a subject may have encoded in ways suggested by particular distractors, he still may be able to choose the correct word. Or he may have encoded in ways not represented by the distractors.

Evidence has been accumulating to suggest that a long-term memory is a collection of information or of attributes that can serve in discriminating it from other memories and can function as retrieval cues. In addition to verbal attributes, visual images may be a part of the memory; emotional responses produced at the time the memory is established may be incorporated.

"Tip-of-the-tongue" phenomenon

The common experience of having a name or word on the tip of the tongue seems related to specific perceptual attributes. In particular, people who report the "tip-of-the-tongue" feeling tend to identify the word's first letter and number of syllables with an accuracy that far exceeds mere guessing. There is evidence that memories may encode information about when they were established and about how often they have been experienced. Some seem to embrace spatial information; *e.g.*, one remembers a particular news item to be on the lower right-hand side of the front page of a newspaper. Research indicates that the rate of forgetting varies for different attributes. For example, memories in which auditory attributes seem dominant tend to be more rapidly forgotten than those with minimal acoustic characteristics.

If a designated (target) memory consists of a collection of attributes, its recall or retrieval should be enhanced by any cue that indicates one of the attributes. For example, on failing to recall the term horse (included in a list just seen), one may be told that there was an animal name among the words. Or he may be asked if an associate term (say, barn or zebra) helps him think of a word he missed. While some additional recall has been observed with this kind of help, failures are common even with ostensibly relevant cues. Though it is possible that the cues frequently are inappropriate, nevertheless, if words were not learned (encoded or stored) with accompanying attributes, cuing of any kind should be ineffective.

THEORIES OF FORGETTING

When memory of past experience is not activated for days or months, forgetting tends to occur; and any theory of forgetting must cope with this primitive observation. Such auxiliary phenomena as differences in the rates of forgetting for different kinds of information also must be accommodated.

It has been theorized that as time passes the physiological bases of memory tend to change. With disuse, it is held that the neural engram (the memory trace in the brain) gradually decays or loses its clarity. While such a theory seems reasonable, it would, if left at this point, do little more than restate behavioral evidence of forgetting at the nervous-system level. Decay or deterioration does not seem attributable merely to the passage of time; some underlying physical process needs to be demonstrated. Until a neurochemical basis for memory can be more explicitly described, any decay theory of forgetting must await detailed development.

Interference theory; retroactive and proactive inhibition

A pre-eminent theory of forgetting at the behavioral level is anchored in the phenomena of interference; in what are called retroactive and proactive inhibition. In retroactive inhibition, new learning interferes with retention of the old; in proactive inhibition, old memories interfere with the retention of new ones. Both phenomena have great generality in studies of any kind of learning, although most research among humans has considered verbal learning.

People may, for example, learn two successive verbal lists; the next day some are asked to recall the first list and others to recall the second. Still a third (control) group learns only one list and is asked to recall it a day later. People who learn two lists almost unfailingly will recall much less than do those in the control group. The amount by which controls exceed those who recall the first list is a measure of retroactive inhibition; the degree to which they are better than those who recall the second list is a measure of proactive inhibition. While retroactive inhibition usually will be observed in relearning, it is unusual to detect proactive deficit under such circumstances.

Theorists attribute the loss produced by these procedures to interference between list-learning tasks. When lists are constructed to exhibit varying differences, the degree of interference seems to be related to the amount of similarity. Thus loss in recall will be reduced when two successive lists have no identical terms. Maximum loss generally will occur when there appears to be heavy (but not complete) overlap in the memory attributes for the two lists. One may recall parts of the first list in trying to remember the second and vice versa. (This breakdown in discrimination may reflect the presence of dominant attributes that are appropriate for items in both lists.) Discrimination tends to deteriorate as the number of lists increases, retroactive and proactive inhibition increasing correspondingly, suggesting interference at the time of recall.

In retroactive inhibition, however, all of the loss need not be attributed to competition at the moment of recall. Some of the first list may be lost to memory in learning the second; this is called unlearning. If one is asked to recall from both lists combined, first-list items are less likely to be remembered than if the second list had not been learned. Learning the second list seems to act backward in

time (retroactively) to destroy some memory for the first. So much effort has been devoted to studying conditions that affect unlearning that it has become a major topic in interference theory.

Retroactive and proactive effects can be quite gross quantitatively. If one learns a list one day and tries to recall it the next, learns a second list and attempts recall for it the following day, learns a third and so on, recall for each successive list tends to decline. Roughly 80 percent recall may be anticipated for the first list; this declines steeply to about 20 percent for the tenth list. Learning the earlier lists seems to act forward in time (proactively) to inhibit retention of later lists. These proactive phenomena indicate that the more one learns the more rapidly one will forget. Similar effects can be demonstrated for retroactive inhibition within just one laboratory session.

Such powerful effects have led some to theorize that all forgetting is produced by interference. Any given memory is said to be subject to interference from others established earlier or subsequently. Interference, theoretically, may occur when memories conflict through any attributes. With a limited group of attributes and an enormous number of memories, it might seem that everyday attempts to recall would be chaotic.Yet even if all of the memories shared some information, other attributes not held in common could still serve to distinguish them. For example, every memory theoretically is encoded at a different time and temporal attributes might serve to discriminate otherwise conflicting memories. Indeed, when two apparently conflicting lists are learned several days apart, proactive inhibition is markedly reduced. Assuming memories to be multiple-encoded, interference theory need not predict utter confusion in remembering.

Limits on interference

Sources of interference are most pervasive and should not be considered narrowly. For example, any memory seems to be established in specific surroundings or context, and subsequent efforts to remember tend to be less effective when the circumstances differ from the original. Alcoholics, when sober, tend to have trouble finding bottles they have hidden while intoxicated; when they drink again, the task is much easier. Some contexts also may be associated with other memories that interfere with whatever it is that one is trying to remember.

Each new memory tends to amalgamate information already in long-term storage. Encoding mechanisms invariably adapt or relate fresh data to information already present, to the point that what is coded may not be a direct representation of incoming stimuli. This is particularly apparent when input is relatively meaningless; the newly encoded memory comes to resemble those previously established (*i.e.*, it accrues meaning). For example, a nonsense word such as LAJOR might be encoded as MAJOR.

To recall any nonsense word correctly requires that an appropriate decoding rule be a part of the memory; but coding rules are subject to forgetting (interference) in the same way that any attribute is. Qualitative changes in memory may result when the information presented does not allow precise decoding; thus, when one sees a drawing of a jagged figure that resembles a star he might encode it as a star, knowing full well that it is not perfect. Subsequent decoding in recall (or recognition) thus produces only an approximation of the original jagged figure; it may well be influenced by other equally imprecise decoding rules already stored. In like fashion, somewhat incoherent sentences may become more reasonable during encoding; they tend to be reproduced in memory tests more coherently. When the learner has trouble making sense of any new stimulus (when he cannot specify encoding and decoding rules with precision) the decoded memory tends to resemble previously established memories.

Although interference has attracted wide support as an account of forgetting, it must be placed in perspective. Interpretations that emphasize distinctions between short- and long-term memory and that posit control processes for handling information are potentially more comprehensive than is interference theory. Behavioral evidence for interference eventually may be explained within such systems.

In addition, a number of deductions from interference theory have not been well supported by experiment. The focus of difficulty lies in the hypothesis that interference from established memories is a major source of proactive inhibition. The laboratory subject is asked to learn tasks with attributes that have varying degrees of conflict with memories established in daily life. Theoretically, the more conflict, the greater the proactive interference to produce forgetting. Yet a number of experiments have failed to provide much support for this prediction.

Interference theory also fails to account for some pathological forms of forgetting. Repression as observed in psychiatric practice, for example, represents almost complete, highly selective forgetting, far beyond that anticipated by interference theorists. Attempts to study repression through laboratory procedures have failed to yield systematic data that could be used to test theoretical conclusions.

CORRELATES OF RATE OF FORGETTING

Although forgetting normally is expected to begin as soon as practice ceases, at times an exception (known as reminiscence) has been reported. In reminiscence, memory seems to improve without practice; retention is even better if tested after a rest period than if tested immediately after learning trials stop. Observed only over periods of a few minutes, this elusive phenomenon produces very small improvements, and forgetting follows. Scores of studies designed to elicit reminiscence have failed to do so, yielding only evidence of forgetting. Reasons for the conflicting findings have not been identified.

Reminiscence

Degree of learning. The degree of learning is found to be directly associated with the amount of practice. In a metaphoric sense, specific memory may be said to grow stronger and stronger as practice proceeds. Even after a task can be performed or recited perfectly, continued practice (sometimes called overlearning) increases the "strength" of the memory. The rate of forgetting is slower when the degree of learning is greater. If there were one universal prescription for resisting forgetting, it would be to learn to a very high level initially; results seem even better when learning trials are not bunched together. Practice trials may be given en masse in a single session or the same number of trials may be distributed in sessions held on different days. The interrupted schedule is far superior to massed practice in that the rate of forgetting that follows distributed practice is much slower. The laboratory evidence also confirms the belief that cramming for an examination may produce acceptable performance shortly afterwards, but that such massed study results in poor long-term retention. Information learned in widely distributed practice appears less susceptible to interference; memories established under distributed schedules also are less likely to produce proactive inhibition than are those learned in massed trials.

Mnemonic systems. The principle that new information is encoded to previously stored data has been used in an effort to aid memory function. When encoding techniques are formally applied, they are called mnemonic systems or devices. (The popular rhyme that begins "Thirty days hath September . . . " is an example.) Verbal learning can be enhanced by providing an appropriate mnemonic system (even to a bright college student who may have devised efficient systems of his own). Thus, paired associates (*e.g.*, DOG-CHAIR) will be learned more rapidly if they are included in a simple sentence (*e.g.*, The dog jumped over the chair). Imagery that can relate different words to be learned (even in a bizarre fashion) has been found beneficial. Some investigators hold that pure rote learning (in which no use is made of established memories except to directly perceive the stimuli) is rare or nonexistent. They suggest that all learning elaborates on memories already available. This could be taken to mean that the rate of forgetting would be the same whether or not a formal mnemonic system were used in learning.

Indeed, there seem to be no experimental results in which formal mnemonic instruction has resulted in forgetting more rapidly than when such special training is not given. Yet, while there often is no difference in the rate of forgetting, a number of studies indicate slower forgetting following instruction in a mnemonic system. These

discrepancies may mean that some mnemonic systems are more subject to interference than are others. Perhaps the methods used fail to adequately distinguish between learning and forgetting.

Rates of learning and forgetting

Factors that influence the rate of learning should be distinguished from those that affect the rate of forgetting. For example, nonsense syllables are learned more slowly than are an equal number of common words; if both are studied for the same length of time, the better learned common words will be forgotten more slowly. But this does not mean that rate of forgetting *intrinsically* differs for the two tasks. Degree of learning must be held constant before it may be judged whether there are differences in rate of forgetting. Rates of forgetting can be compared only if tasks are learned to an equivalent degree. Indeed, when degree of learning is experimentally controlled, different kinds of information are forgotten at about the same rate. Nonsense syllables are *not* forgotten more rapidly than are ordinary words. In general, factors that seem to produce wide differences in rate of learning show little (if any) effect on rate of forgetting. (Despite discrepant evidence, mnemonic systems may prove an exception.)

Individual differences. Experimental findings seem to contradict the common intuition that people inherently differ in the rate at which they forget. This intuitive belief appears largely to derive from definite, wide individual differences in rate of learning; some people do learn faster than others. Thus, given the same number of trials or identical time in which to study, people will vary widely in the level of learning they achieve. Individual differences in forgetting then can be predicted efficiently, merely on the basis of how well each person has learned. This powerfully indicates that ordinary estimates of one's rate of forgetting are spurious, being obscured by uncontrolled differences in learning ability. One's talent for learning seems to swamp efforts to assess his inherent tendency to forget. Under less ordinary circumstances, however (*e.g.*, selective brain injury, stroke, neurotic amnesia), the degree of learning does seem to be almost completely irrelevant to the rate at which one forgets. An amnesia sufferer may forget his own name and still may be able to remember that Sofia is the capital of Bulgaria (see below). (B.J.U./Ed.)

Abnormalities of memory

Disorders of memory must have been known to the ancients and are mentioned in several early medical texts; but it was not until the closing decades of the 19th century that serious attempts were made to analyze them or to seek their explanation in terms of brain disturbances. Of the early attempts, the most influential was that of a French psychologist, Théodule-Armand Ribot, who, in his *Diseases of Memory* (1881, English translation 1882), endeavoured to account for memory loss as a symptom of progressive brain disease by embracing principles describing the evolution of memory function in the individual, as offered by an English neurologist, John Hughlings Jackson. Ribot wrote:

Ribot's "law"

> The progressive destruction of memory follows a logical order—a law. It advances progressively from the unstable to the stable. It begins with the most recent recollections, which, being lightly impressed upon the nervous elements, rarely repeated and consequently having no permanent associations, represent organization in its feeblest form. It ends with the sensorial, instinctive memory, which, having become a permanent and integral part of the organism, represents organization in its most highly developed stage.

The statement, amounting to Ribot's "law" of regression (or progressive destruction) of memory, enjoyed a considerable vogue and is not without contemporary influence. The notion has been applied with some success to phenomena as diverse as the breakdown of memory for language in a disorder called aphasia and the gradual return of memory after brain concussion. It also helped to strengthen the belief that the neural basis of memory undergoes progressive strengthening or consolidation as a function of time. Yet students of retrograde amnesia (loss of memory for relatively old events) agree that Ribot's principle admits of many exceptions. In recovery from concussion of the brain, for example, the most recent memories are not always the first to return. It has proved difficult, moreover, to disentangle the effects of passage of time from those of rehearsal or repetition on memory.

A Russian psychiatrist, Sergey Sergeyevich Korsakov (Korsakoff), may have been the first to recognize that amnesia need not necessarily be associated with dementia (or loss of the ability to reason), as Ribot and many others had supposed. Korsakov described severe but relatively specific amnesia for recent and current events among alcoholics who showed no obvious evidence of shortcomings in intelligence and judgment. This disturbance, now called the Korsakoff syndrome, has been reported for a variety of brain disorders aside from alcoholism and appears to result from damage in a relatively localized part of the brain.

The neurological approach may be combined with evidence of psychopathology to enrich understanding of memory function. Thus, a French neurologist, Pierre Janet, described amnesia sufferers who were apparently very similar to those observed by Korsakov but who gave no evidence of underlying brain disease. Janet also studied people who had lost memory of extensive periods in the past, also without evidence of organic disorder. He was led to regard these amnesias as hysterical, explaining them in terms of dissociation: a selective loss of access to specific memory data that seem to hold some degree of emotional significance. In his experience, reconnection of dissociated memories could as a rule be brought about by suggestion while the sufferer was under hypnosis. Freud regarded hysterical amnesia as arising from a protective activity or defense mechanism against unpleasant recollections; he came to call this sort of forgetting repression, and he later invoked it to account for the typical inability of adults to recollect their earliest years (infantile amnesia). He held that all forms of psychogenic (not demonstrably organic) amnesia eventually could resolve after prolonged sessions of talking (psychotherapy) and that hypnosis was neither essential nor necessarily in the amnesiac's best interest. Nevertheless, hypnosis (sometimes induced with the aid of drugs) has been widely used in the treatment of hysterical amnesia, particularly in time of war when only limited time is available.

Repression

ORGANIC DISORDERS

Defect of memory is one of the most frequently observed symptoms of impaired brain function. It may be transitory, as after an alcoholic bout or an epileptic seizure; or it may be enduring, as after severe head injury or in association with brain disease. When there is impaired ability to store memories of new experiences (up to total loss of memory for recent events) the defect is termed anterograde amnesia. Retrograde loss may progressively abate or shrink if recovery begins, or it may gradually enlarge in scope, as in cases of progressive brain disease. Minor grades of memory defect are not uncommon aftereffects of severe head injury or infections such as encephalitis; typically they are shown in forgetfulness about recent events, in slow and insecure learning of new skills, and sometimes in a degree of persistent amnesia for events preceding the illness.

Transient global amnesia. Apparently first described in 1964, transient global amnesia consists of an abrupt loss of memory lasting from a few seconds to a few hours, without loss of consciousness or other evidence of impairment. The individual is virtually unable to store new experience, suffering permanent absence of memory for the period of the attack. There is also a retrograde loss that may initially extend up to years preceding the attack. This deficit shrinks rapidly in the course of recovery but leaves an enduring gap in memory that seldom exceeds the three-quarters of an hour before onset. Thus the person is left with a persisting memory gap only for what happened during the attack itself and in a short period immediately preceding. Such attacks may be recurrent, are thought to result from transient reduction in blood supply in specific brain regions, and sometimes presage a stroke.

Traumatic amnesia. On recovery of consciousness after trauma, a person who has been knocked out by a blow on the head at first typically is dazed, confused, and imper-

fectly aware of his whereabouts and circumstances. This so-called posttraumatic confusional state may last for an hour or so up to several days or even weeks. While in this condition, the individual appears unable to store new memories; on recovery he commonly reports total amnesia for the period of altered consciousness (posttraumatic amnesia). He also is apt to show retrograde amnesia that may extend over brief or quite long periods into the past, the duration seeming to depend on such factors as severity of injury and the sufferer's age. In the gradual course of recovery, memories are often reported to return in strict chronological sequence from the most remote to the most recent, as in Ribot's law. Yet this is by no means always the case; memories seem often to return haphazardly and to become gradually interrelated in the appropriate time sequence. The amnesia that remains seldom involves more than the events that occurred shortly before the accident though in severe cases careful inquiry may reveal some residual memory defect for experiences dating from as long as a year before the trauma. It is thought by some that, after recovery, the overall period of time for which there is no recollection may indicate the degree of severity of the head injury.

Haphazard recovery of memory

Traumatic automatism. Posttraumatic amnesia is sometimes observed after mild head injury without loss of consciousness and with no apparent change in ordinary behaviour. A football player who is dazed but not knocked out by a blow on the head, for example, may continue to play and even score a goal. But he may be going through these motions automatically and may later have no memory whatever of the part of the game that followed his injury. The phenomenon is known as traumatic automatism and seems similar to, if not identical with, transient global amnesia.

Memory defect after electroconvulsive therapy. Electroconvulsive treatments have been widely used in psychiatry, particularly for depressed people. A seizure or convulsion is induced by passing current through electrodes placed on the forehead. Each treatment is followed by a period of confusion for which the person is subsequently amnesic; at this time there is also a rapidly abating amnesia of some seconds for events that immediately preceded the shock. After a number of treatments, however, some individuals complain of more persistent memory defect, shown mainly in exaggerated forgetfulness for day-to-day events. These difficulties nearly always clear up within a few weeks after treatment ends. Experimental evidence tentatively suggests that electroshock administered to only one side of the head produces therapeutic results equal to those of the standard procedure but with significantly reduced impairment of memory.

Korsakoff's syndrome. First described in cases of chronic alcoholism, Korsakoff's psychosis, or syndrome, occurs in a wide variety of toxic and infectious brain illnesses, as well as in association with such nutritional disorders as deficiency of the B vitamins. The syndrome also has been observed among people with cerebral tumours, especially those involving the third ventricle (one of the fluid-filled cavities in the brain). The main psychological feature is gross defect in recent memory, sometimes so severe as to produce "moment-to-moment" consciousness; such people can store new information only for a few seconds and report no continuity between one experience and the next. They seem incapable of learning, even after many trials or repetitions. Although cases of such severity are relatively rare, the ability to store experience only briefly is quite characteristic of Korsakoff's syndrome.

In addition, sufferers almost always show evidence of retrograde amnesia that can span as little as a few weeks past to as much as 15 or 20 years before onset of the disorder. These extensive retrograde amnesias are seldom total or uniform, and "islands" of memory often can be found by persistent interrogation. The person's memory function depends heavily on circumstances; for example, a man with Korsakoff's syndrome who recognizes his wife instantly when she visits may in her absence vehemently deny that he is married. Commonly, there is disorientation in place and time; the individual often underestimates his own age, sometimes grossly. Some sufferers characteristically confabulate; *i.e.*, they remember experiences they never personally had or they falsely localize their memories in time. Sufferers sometimes deny their illness or memory problems. Otherwise, they can exhibit good intelligence and, apart perhaps from some lack of spontaneity, may show little or no personality change.

Extensive retrograde amnesia

While Korsakoff's syndrome is commonly encountered as a transitory sign of brain disorder, it can be chronic, remaining effectively unimproved over many years. Even with improvement, however, an appreciable weakness in recent memory, particularly in regard to sequence in time, is quite apparent.

Persistent defect after encephalitis. Attention repeatedly has been drawn to severe and persistent memory defect following attacks of a form of brain inflammation called acute inclusion body encephalitis. The individual's behaviour closely resembles that of Korsakoff's syndrome except that his insight into the memory disorder is usually good and confabulation is infrequent or absent. Indeed, the memory disorder is sometimes so limited and specific as to raise the possibility of a psychogenic (*i.e.*, hysterical) amnesia. In cases of this kind there may be little or no impairment of intelligence or judgment.

Defect following brain surgery. Surgical operations on the sides of the brain (the temporal lobes) to remove tissues that produce symptoms of epilepsy are routine. While good results are often achieved, a degree of memory defect ensues. Operations on the dominant (usually left) temporal lobe tend to hamper one's ability to learn verbal information by hearing or reading. Usually observable even before surgery, the defect tends to be more marked after operation and has been reported to persist for up to three years before eventual recovery. Operations on one temporal lobe when there is unsuspected damage to its fellow on the other side of the brain (or on both lobes, in surgery very rarely undertaken) produce severe and persistent general memory defect, altogether comparable to postencephalitic amnesia. There is gross defect in recent memory and in learning (except perhaps in motor learning), with retrograde amnesia that initially may involve several years of the person's past. Intelligence otherwise appears to be well preserved; the individual shows insight into his memory difficulty, and seldom, if ever, confabulates.

Diffuse brain diseases. Some memory failure is almost universal during old age, particularly in forgetfulness for names and in the reduced ability to learn. Many people of advanced age, nevertheless, show adequate memory function if they suffer no brain disease. Impairment of memory is a characteristic early sign of senility, as well as of hardening of the brain arteries (cerebral arteriosclerosis) at any age, with exaggerated forgetfulness for recent events and progressive failure in memory for experiences that preceded the disorder. As arteriosclerotic brain disease progresses, amnesia tends to extend further into the past, embracing personal experience and general or common information. When the symptoms are almost those of Korsakoff's syndrome, the disturbance is called presbyophrenia. In most cases the amnesia is complicated by failure in judgment and changes in character. It has been suggested that severe memory defect in an elderly person carries a poor prognosis, being related to such factors as a shortened survival time and an increased death rate.

Senility

A Swiss psychiatrist, Eugen Bleuler, held that amnesia results only from a diffuse disorder of the outer layers (cortex) of the brain and suggested that memory depends on the integrity of the cortex as a whole. Indeed, the removal of brain tissue from rats and monkeys in experimental studies has indicated that retention of complex habits by the animals depends on the total amount of cortex that remains. It was claimed that the degree to which memory is lost depends not on where the brain is injured but on the extent of the damage. (This is the "law" of mass action, which asserts that the brain functions in a unitary manner; *i.e.*, as a whole.) While the extent of diffuse brain damage is roughly related to the severity of memory defect, the principle of mass action is manifestly inadequate. Whatever its physical basis, memory seems to depend on the integrity of relatively limited parts of the brain, rather than on that organ (or even the cortex) as a whole.

Brain structures in amnesia

Severe and highly specific amnesic symptoms principally stem from damage to such brain structures as the mammillary bodies, circumscribed parts of the thalamus, and of the temporal lobe (*e.g.*, the hippocampus). While the ability to store new experience (and perhaps to retrieve well-established memories) appears to depend on a distinct neural system involving the temporal cortex and limited parts of the thalamus and hypothalamus, understanding of the neuroanatomy of memory remains sketchy enough to generate major differences of opinion. French and German workers tend to stress the role of the mammillary bodies, while U.S. investigators tend to implicate the thalamus. It has been pointed out that circumscribed damage to the mammillary bodies is not invariably associated with memory defect; cases of amnesia evidently occur in which these structures are spared. Nevertheless, implication of the mammillary bodies in a large number of verified cases of Korsakoff's syndrome seems incontrovertible. Injury to other neural tissues (*e.g.*, the so-called fornix bundle deep within the brain) that anatomically might be expected to produce severe memory disorder rarely does so. While evidence for amnesia as a sign of localized brain damage is impressive, much remains to be understood about the physical system that sustains memory.

PSYCHOLOGICAL STUDIES OF AMNESIA

Short-term memory. The so-called short-term memory is typically intact among amnesia sufferers. Such victims usually can repeat a short phrase or a series of words or numbers from immediate memory as adequately as anyone of comparable age and intelligence. Such an amnesic person can retain the gist of a question or request long enough to respond appropriately, unless, of course, there is enough delay in performance or attention is diverted. Evidently the ability to register information is intact, if this means availability of data in short-term memory. Thus, experimental psychologists who favour a sharp distinction between short-term and long-term storage systems contend that the primary deficit in amnesia is an inability to transfer information from short-term to long-term storage.

Associative learning. It has been argued that the basic deficit in the amnesic state is a loss of learning ability. In a series of experiments with amnesic patients, using, for the most part, verbal material, the subjects evidenced failure to link new with old associations, rapid fading of new associations, and great difficulty in reproducing whatever associations might have been formed. These findings have been amply confirmed. In one view, however, the weakness resides less in the failure to establish new associations than in their rapid decay (*i.e.*, accelerated forgetting). On the other hand, it has often been noticed that if a Korsakoff patient can once succeed in learning an item, he may be able to reproduce it correctly after an appreciable interval of time. Further experiments, using a variety of techniques for assessing learning and retention, have suggested that retrieval rather than learning is at fault.

Motor skill. It has been noted that the fact that the acquisition of manual skill in Korsakoff patients is less impaired than either verbal learning or the solution of puzzles or mazes. This is confirmed in the observation that a severely amnesic patient who had undergone an extensive operation on the temporal lobes could perform rotary-pursuit and tracking tasks at a level not greatly inferior to that of healthy subjects. A second case of the same kind has been described, in which memory for motor tasks such as maze learning or the rendering of new compositions on the piano is said to have been completely preserved. These observations suggest that the acquisition of motor skill may remain relatively unaffected by lesions that give rise to a severe defect of general memory. What is commonly called global or generalized memory defect may, therefore, become increasingly subject to fractionation.

Generalized versus specific memory loss

Residual learning capacity. Korsakov himself pointed out that a patient who consistently denies having seen his doctor before does not necessarily react to him on each successive encounter as a total stranger. It thus appears that, despite gross amnesia, some learning, perhaps implicit, can still take place. This view has gained much support from clinical and experimental studies. About 1900 it was reported that even severely affected Korsakoff patients show appreciable savings in relearning verbal material after an interval of several hours or days, thus indicating minimal retention. Some Korsakoff patients, in spite of gross amnesia, eventually learn their way about the hospital. Again, some patients who disown any knowledge of their whereabouts may nevertheless give the correct name of the hospital, when asked to guess or to select it from a list containing the names of several hospitals. Thus, while learning capacity is seldom, if ever, wholly destroyed, there is failure to integrate new knowledge within the total personality. It is apparently a lack of mental cohesion that lies at the basis of Korsakoff's psychosis.

Forgetting. While some clinicians have attributed memory defect largely to defective registration of experience (*i.e.*, failure to form memory traces), the widely accepted view is that it results primarily from a greatly increased rapidity of forgetting (*i.e.*, rapid decay of memory traces). This view has also been held by the great majority of experimental psychologists who have worked with amnesic people. The consensus is that amnesia sufferers characteristically lose much of the memory they once had. This conclusion finds support in the very rapid extinction of conditioned eyeblink responses to a buzzer. It is notable that, in Korsakoff states, forgetting appears to be due to the passage of time (oblivescence) rather than to retroactive inhibition or some kindred interference effect.

Time disorders. Estimation of time is typically poor in amnesic states. The individual is prone to underestimate grossly the time in which he has been engaged on any particular activity. Conversely, he may equally grossly overestimate the time that has elapsed since a particular event (*e.g.*, the visit of a relative) of which he has preserved some recollection. Indeed, amnesic patients exhibit a remarkable want of coherence in their thought processes, suggesting that a lack of temporal synthesis underlies, and may indeed in large part explain, the defect of memory. Yet although difficulties in dating particular past events and in building a coherent time framework are characteristic of amnesic states and may persist after otherwise good recovery, an explanation couched wholly in terms of time disturbance is scarcely convincing.

Retrograde amnesia. Since retrograde amnesia relates to memory for events that took place when brain function was unimpaired, it clearly cannot be ascribed to failure of registration—with the exception, perhaps, of the very brief permanent amnesias following electroconvulsive shock or head injury. Retrograde amnesia otherwise would appear to be wholly due to a failure of retrieval, though this failure is evidently selective. That recent memories are generally harder to evoke than those more remote is usually explained on the basis of consolidation; *i.e.*, progressive strengthening of memory traces with the passage of time. Yet, recency is not the only factor, and in some cases memory for a relatively recent event may still be preserved while that for one more remote is inaccessible. Much depends, too, on the method used to test retrieval; *e.g.*, recognition may succeed when voluntary recall entirely fails. By and large, the availability of information in memory would seem to depend to a considerable extent on its relation to the person's current interests and preoccupations. When these are severely curtailed by an amnesic state, the links connecting present and past are severed, with a consequent failure of reproduction.

Consolidation of the memory trace

PSYCHOGENIC AMNESIA

Some forms of amnesia appear to be quite different from those associated with detectable injury or disease of the brain. These comprise, first, amnesias that can be induced in apparently normal individuals by means of suggestion under hypnosis; and secondly, amnesias that arise spontaneously in reaction to acute conflict or stress, and which are commonly called hysterical. Such amnesias are reversible and have been explained wholly in psychological terms. Nevertheless, organic factors are not infrequently involved to some extent, and the distinction between organic and psychogenic amnesia may turn out to be far less absolute than has been supposed.

Hypnotic amnesia. Memory of a hypnotic trance is

often vague and fragmentary, as in awakening from an ordinary dream. This may be due in part to defect of registration during the period of altered consciousness. At the same time, very much more complete posthypnotic amnesia can be induced if an individual is told that, when he awakens, he will remember nothing of what went on during the period of hypnosis. This is clearly a psychogenic phenomenon; memory is fully regained if the patient is rehypnotized and an appropriate counter-suggestion given. It may also be regained if the person is persistently interrogated in the waking state, again suggesting that the amnesia is apparent rather than real. This observation led Freud to seek access to ostensibly forgotten (repressed) memories in his patients without the use of hypnosis.

Hysterical amnesia. Hysterical amnesia is of two main types. One involves the failure to recall particular past events or those falling within a particular period of the patient's life. This is essentially retrograde amnesia but it does not appear to depend upon an actual brain disorder, past or present. In the second type there is failure to register—and, accordingly, later to recollect—current events in the patient's ongoing life. This is essentially anterograde amnesia and, as an ostensibly psychogenic phenomenon, would appear to be rather rare and almost always encountered in cases in which there has been a preexisting amnesia of organic origin. Rarely, amnesia appears to cover the patient's entire life, extending even to his own identity and all particulars of his whereabouts and circumstances. Although most dramatic, such cases are extremely rare and seldom wholly convincing. They usually clear up with relative rapidity, with or without psychotherapy.

Hysterical amnesia differs from organic amnesia in important respects. As a rule it is sharply bounded, relating only to particular memories, or groups of memories, often of direct or indirect emotional significance. It is also usually motivated in that it can be understood in terms of the patient's needs or conflicts; *e.g.*, the need to seek financial compensation after a road accident causing a mild head injury or to escape the memory of an exceptionally distressing or frightening event. Hysterical amnesia also may extend to basic school knowledge, such as spelling or arithmetic, which is never seen in organic amnesia unless there is concomitant aphasia or a very advanced state of dementia. A most distinctive feature of hysterical amnesia is that it can almost always be relieved by such procedures as hypnosis. Although distinguishing organic from psychogenic amnesia is not always easy, it can usually be achieved on the basis of such criteria, especially when there is no reason to suspect actual brain damage.

Relief of amnesia through hypnosis

Legal implications. The differentiation of organic from functional amnesia not uncommonly assumes legal importance, as in cases in which compensation is sought for disability held to be due to industrial or road accidents causing head injuries. If there is a complaint of defective memory, it is legally important to ascertain what part of it can be ascribed to the aftereffects of the head injury and what part of it to subsequent psychogenic elaboration. Similar issues may also arise on occasion in criminal cases, as in a trial in England (1959) in which it was contended that the accused man had a total amnesia for the circumstances of his alleged offense—the murder of a police officer—and should therefore be regarded as unfit to plead. After much discussion as to whether the amnesia was organic, hysterical, or feigned, the jury found it not to be genuine and the trial proceeded to conviction.

Mixed amnesic states. Students of amnesia have been increasingly impressed by the frequency with which psychogenic factors appear to reinforce, prolong, or otherwise complicate an organic memory defect. Hysterical reactions appear to be far from uncommon in brain-damaged patients: conversely, there is little or nothing in the pathology of hysterical amnesia that has not been observed in the organic syndrome. One case reported in the German literature in 1930 aroused great controversy. A young man developed severe and persistent amnesia following accidental carbon monoxide poisoning. His consciousness was virtually restricted to a second or two and no lasting memory traces could apparently be formed. While the original defect of memory may have been largely, if not wholly, organic, it was sustained thereafter on a hysterical basis. Conversely, a case has been reported in which the diagnosis, originally hysterical amnesia, had to be altered in light of the discovery that the patient had suffered from progressive brain disease. In such cases, organic and psychogenic factors appear to interact to produce complex and atypical symptoms.

Fugue states. The fugue is a condition in which the individual wanders away from his home or place of work for periods of hours, days, or even weeks. One celebrated case was that of the Rev. Ansell Bourne, described by the U.S. psychologist William James. This clergyman wandered away from home for two months and acquired a new identity. On his return, he was found to have no memory of the period of absence, though it was eventually restored under hypnosis. In not all cases, however, is the basis of the fugue so manifestly psychogenic. Indeed, close observation in some instances may reveal minor alterations in consciousness and behaviour that suggest an organic basis, probably epileptic. According to one view, pathological wandering with subsequent amnesia is due to a constellation of factors, among which are a tendency toward periodic depression, history of a broken home in childhood, and predisposition to states of altered consciousness, even in the absence of organic brain lesion. Psychoanalysts, on the other hand, see in the fugue a symbolic escape from severe emotional conflict.

Possible basis in epilepsy

PARAMNESIA AND CONFABULATION

The term paramnesia was introduced by a German psychiatrist, Emil Kraepelin, in 1886 to denote errors of memory. He distinguished three main varieties; one he called simple memory deceptions, as when one remembers as genuine those events imagined or hallucinated in fantasy or dream. This is not uncommon among confused and amnesic people and also occurs in paranoid states. Kraepelin also wrote of associative memory deceptions, as when a person meeting someone for the first time claims to have seen him on previous occasions. This has been renamed reduplicative paramnesia or simply reduplication. Lastly there was identifying paramnesia, in which a novel situation is experienced as duplicating an earlier situation in every detail; this is now known as déjà vu or paramnesia *tout court*. The term confabulation denotes the production of false recollections generally.

Déjà vu. The déjà vu experience has aroused considerable interest and is occasionally felt by most people, especially in youth or when they are fatigued. It has also found its way into literature, having been well described by, among other creative writers, Shelley, Dickens, Hawthorne, Tolstoy, and Proust. The curious sense of extreme familiarity may be limited to a single sensory system, such as the sense of hearing, but as a rule it is generalized, affecting all aspects of experience including the subject's own actions. As a rule, it passes off within a few seconds or minutes, though its repercussions may persist for some time. For some epileptics, however, déjà vu may continue for hours or even days and can provide a fertile subsoil for delusional elaboration.

In view of its occurrence among organically healthy individuals, déjà vu commonly has been regarded as psychogenic and as having its origin in some partly forgotten memory, fantasy, or dream. This explanation has appealed strongly to psychoanalysts; it also gains support from the finding that an experience very similar to déjà vu can be induced in normal people by hypnosis. If a picture is presented to a hypnotized person with the instruction to forget it and then is shown with other pictures when he is awake, the subject may report an intense feeling of familiarity that he is at a loss to justify. The déjà vu phenomenon also is attributable to minor neurophysiological abnormality; it is frequent in epilepsy. Indeed, déjà vu is accepted as a definite sign of epileptic activity originating in the temporal lobe of the brain and may occur as part of the seizure activity or frequently between convulsions. It seems to be more frequent in cases in which the disorder is in the right temporal lobe and has on occasion been evoked by electrical stimulation of the exposed brain during surgery. Some have been tempted

Hypnotic induction of déjà vu

to ascribe it to a dysrhythmic electrical discharge in some region of the temporal lobe that is closely associated with memory function.

Reduplicative paramnesia. Reduplication is observed mainly among acutely confused or severely amnesic people; for example, a patient may say that he has been in one or more hospitals that are very similar to his present location and that all bear the same name. The effect also can be induced by showing the person an object such as a picture and by testing him for recognition of the same picture a few minutes later. He is apt to say that he has seen a similar picture but definitely not the one now being shown. This effect appears to depend on loss of a sense of familiarity and on failure to treat a single object seen on a number of occasions as one and the same. It has been reported that reduplication of this kind is typically associated with confabulation, speech disorder (paraphasia), disorientation, and denial of illness.

Confabulation. Spurious memories or fabrications are very common in psychiatric disorders and may take on an expansive and grandiose character. They may also embody obvious elements from fantasy and dream. At a more realistic level, the production of false memories (confabulation) is best studied among sufferers of Korsakoff's syndrome, for whom consciousness and reasoning remain clear. When asked what he did on the previous day, such a person may give a detailed account of a typical day in his life several months or years earlier. Evidently his retrograde amnesia and his disorientation in time provide fertile soil for false reminiscence. When the confabulation embodies dramatic, fanciful elements, it is the exception rather than the rule.

Confabulation once was regarded as one's reaction to the social embarrassment produced by a memory defect—*i.e.*, as an attempt to fill memory gaps plausibly. Despite this possibility, many severely amnesic patients confabulate little, if at all; and there appears to be no relation between the severity of amnesia and frequency of confabulation. In consequence, individual differences in preamnesic personality have been stressed, particularly in regard to suggestibility. While many patients who confabulate are obviously highly suggestible, precise tests of suggestibility have not been used in most clinical evaluations. It also has been claimed that the superficially sociable, but basically secretive, individual is particularly prone to confabulate. The most critical factor appears to be the sufferer's degree of insight into his disorder; it has been observed that the amnesia sufferer who most strongly denies any lapse in memory is most prone to confabulate. By contrast, it also has been claimed that in chronic Korsakoff states the individual's insight into his condition is no guarantee of freedom from confabulation.

Inventive memory

While confabulation is pathological by definition, all people include an inventive (and thus spurious) element in their remembering. Indeed, it seems valid to say that all remembering depends heavily on reconstruction rather than on mere reproduction alone. Among amnesiacs, reconstruction is especially drastic, inventive, and error-prone, particularly in regard to chronological sequence. The difference, therefore, between normal and grossly amnesic confabulation may well be one of degree rather than kind.

HYPERMNESIA

Enhancement of memory function (hypermnesia) under hypnosis and in some pathological states was frequently described by 19th-century medical writers; for example, cases were recorded of delirious people who would speak fluently in a language they had not had occasion to use for up to 50 or more years and apparently had forgotten. It was then categorically claimed that anyone under hypnosis would recollect events with invariably greater efficiency than in the waking state. It is true that experience inaccessible to ordinary recall sometimes can be recollected under hypnosis; some have attributed this effect to release from emotional inhibition. Nevertheless, evidence indicates that previously memorized material (*e.g.*, poetry) in many cases is reproduced no better under hypnosis than in the waking state.

Memory prodigies. Few individuals who exhibit exceptional memory have been studied extensively. The case of a Russian mnemonist (memory artist), "S," was studied over a period of 30 years, and his story has been delightfully written by a Soviet psychologist (see *Bibliography*). This man's exceptional mnemonic ability seemed largely to depend on an outstandingly vivid, detailed, and persistent visual memory, almost certainly eidetic ("photographic") in nature. "S" also reported an unusual degree of synesthesia, though whether this helped or hindered his feats of memory is not clear. (A person shows signs of synesthesia when he reports that stimulation through one sense leads to experiences in another sense; for example, such a person may say that he sees vivid flashes of colour when he hears music.) Although "S's" highly developed power of concrete visualization made possible feats of memory far beyond the ordinary, he exhibited weakness in abstract thinking.

Photographic memory

Exceptional memory capacity is occasionally observed among mathematicians and others with exceptional talent for lightning calculation. A mathematics professor at the University of Edinburgh, for example, was reported to be capable of remarkable feats of long-term memory for personal experiences, music, and verbal material in either English or Latin. This talented mathematician has been said to recall with complete accuracy a list of 25 unrelated words after only a brief effort to memorize, and to recite the value of pi (an endless number) to a thousand places or more. Likewise, some composers and musicians appear to possess exceptional auditory memory, though no systematic study of their attainments appears to have been made. The anatomical or physiological basis of hypermnesia remains most incompletely understood. (O.L.Z.)

Mental Disorders and Their Treatment

A mental disorder is any illness with significant psychological or behavioral manifestations that is associated with either a painful or distressing symptom or impairment in one or more important areas of functioning. These disorders, in particular their consequences and their treatment, are of more concern and receive more attention now than in the past. Mental disorders have become a more prominent subject of attention for several reasons. They have always been common, but, with the eradication or successful treatment of many of the serious physical illnesses that formerly afflicted humans, mental illness has become a more noticeable cause of suffering and accounts for a higher proportion of those disabled by disease. Moreover, the public has come to expect the medical profession to help it obtain an improved quality of life in mental as well as physical functioning. And, indeed, there has been a proliferation of both pharmacological and psychotherapeutic treatments in this regard. The transfer of many psychiatric patients, some still showing conspicuous symptoms, from mental hospitals into the community has also increased the public's awareness of the importance and prevalence of mental illness.

There is no simple definition of mental disorder that is universally satisfactory. This is partly because mental states or behaviour that are viewed as abnormal or unacceptable in one culture may be regarded as normal or acceptable in another, and in any case it is difficult to draw a line clearly demarcating healthy from abnormal mental functioning.

A narrow definition of mental illness would insist upon the presence of organic disease of the brain, either structural or biochemical. An overly broad definition would define mental illness as simply being the lack or absence of mental health—that is to say, a condition of mental well-being, balance, and resilience in which the individual can successfully work and function and in which he can both withstand and learn to cope with the conflicts and stresses encountered in life. A more generally useful definition than either of the above is that a mental disorder is an illness with significant psychological or behavioral manifestations that occurs in an individual and that is associated either with a painful or distressing symptom, with impairment in one or more important areas of functioning, or with both. The mental disorder may be due to either a psychological, social, biochemical, or genetic dysfunction or disturbance—or a combination of these factors—in the individual.

A mental illness can have an effect on every aspect of a person's life, including thinking, feeling, mood, and outlook and such areas of external activity as family and marital life, sexual activity, work, recreation, and management of material affairs. Most mental disorders negatively affect how individuals feel about themselves and impair their capacity for participating in mutually rewarding relationships.

Psychopathology is the systematic study of the significant causes, processes, and symptomatic manifestations of mental disorders. The meticulous study, observation, and inquiry that characterize the discipline of psychopathology are, in turn, the basis for the practice of psychiatry (*i.e.*, the science and practice of diagnosing and treating mental disorders, as well as dealing with their prevention), clinical psychology, and counseling. Psychiatry and related disciplines embrace a wide spectrum of techniques and approaches for treating mental illnesses. These include the use of psychoactive drugs to correct biochemical imbalances in the brain or otherwise to relieve depression, anxiety, and other painful emotional states.

Another important group of treatments comprises the psychotherapies, which seek to treat mental disorders by psychological means and which involve verbal communication between the patient and a trained person in the context of a therapeutic interpersonal relationship between them. An important variant of this latter mode of treatment is behaviour therapy, which concentrates on changing or modifying observable pathological behaviours by the use of conditioning and other experimentally derived principles of learning.

Types and causes of mental disorders

CLASSIFICATION AND EPIDEMIOLOGY

Psychiatric classification attempts to bring order to the enormous diversity of mental symptoms, syndromes, and illnesses that are encountered in clinical practice. Epidemiology is the measurement of the prevalence, or frequency of occurrence, of these psychiatric disorders in different human populations.

Classification. Diagnosis is the process of identifying an illness by studying its signs and symptoms and by considering the patient's history. Much of this information is gathered by the mental health practitioner (*e.g.,* psychiatrist, psychologist, social worker, or counselor) during initial interviews with the patient, who describes the main complaints and symptoms and any past ones and briefly gives a personal history and current situation. The practitioner may administer any of several psychological tests to the patient and may supplement these with a physical and a neurological examination. These data, along with the practitioner's own observations of the patient and of the patient's interaction with him, form the basis for a preliminary diagnostic assessment. For the practitioner, diagnosis involves finding the most prominent or significant symptoms, upon which the patient's disorder can be assigned to a category as a first stage toward treatment.

Classification systems in psychiatry aim to distinguish groups of patients who share the same or related clinical symptoms in order to provide an appropriate therapy and accurately predict the prospects of recovery for any individual member of that group. Thus, the diagnosis of, for example, depression having been made, it becomes logical to consider antidepressant drugs when preparing a course of treatment.

The diagnostic terms of psychiatry have been introduced at various stages of the discipline's development and from very different theoretical standpoints. Sometimes two words with quite different derivations have come to mean almost the same thing—for example, *dementia praecox* and *schizophrenia.* Sometimes a word, such as *hysteria,* carries many different meanings, depending on the psychiatrist's theoretical orientation.

Psychiatry is hampered by the fact that the cause of many mental illnesses is unknown, and so convenient diagnostic distinctions cannot be made between such illnesses, as they can, for instance, in infectious medicine, where infection with a specific type of bacterium is a reliable indicator for a diagnosis of tuberculosis. But the greatest difficulty presented by mental disorders as far as classification and diagnosis are concerned is that the same symptoms are often found in patients with different or unrelated disorders, or a patient may show a mix of symptoms properly belonging to several different disorders. Thus, although the categories of mental illness are defined according to symptom patterns, course, and outcome, the illnesses of many patients constitute intermediate cases between such categories, and the categories themselves may not necessarily represent distinct disease entities and are often poorly defined.

Mixed symptoms in many mental disorders

The two most frequently used systems of psychiatric classification are the *International Classification of Diseases,* produced by the World Health Organization, and the *Diagnostic and Statistical Manual of Mental Disorders* (DSM), produced by the American Psychiatric Association. The 10th revision of the former, published in 1992, is widely used in western Europe and other parts of the world for epidemiological and administrative purposes. Its nomenclature is deliberately conservative in conception so that it can be used by clinicians and mental health care systems in different countries.

This article, however, will follow the fourth edition of the DSM, which was published in 1994. The DSM differs from the International Classification in its introduction of precisely described criteria for each diagnostic category; its categorizations are usually based upon the detailed description of symptoms.

The DSM-IV has been widely used, especially in the United States, and its detailed descriptions of diagnostic criteria have been useful in eradicating the inconsistencies of earlier classifications. However, there are still some major problems in its everyday clinical use. Chief among these problems is the DSM's innovative and controversial abandonment of the general categories of psychosis and neurosis in its classificatory scheme. These terms have been and still are widely used to distinguish between classes of mental disorders, though there are various mental illnesses, such as personality disorders, that cannot be classified as either psychoses or neuroses.

Psychoses. Psychoses are major mental illnesses that are characterized by severe symptoms such as delusions, hallucinations, disturbances of the thinking process, and defects of judgment and insight. Persons with psychoses exhibit a disturbance or disorganization of thought, emotion, and behaviour so profound that they are often unable to function in everyday life and may be incapacitated or disabled. Such individuals are often unable to realize that their subjective perceptions and feelings do not correlate with objective reality, a phenomenon evinced by persons with psychoses who do not know or will not believe that they are ill despite the distress they feel and their obvious confusion concerning the outside world. Traditionally, the psychoses have been broadly divided into organic and functional psychoses. Organic psychoses were believed to result from a physical defect of or damage to the brain. Functional psychoses were believed to have no physical brain disease evident upon clinical examination. Much recent research suggests that this distinction between organic and functional is probably inaccurate. Most psychoses are now believed to result from some structural or biochemical change in the brain.

Neuroses. Neuroses, or psychoneuroses, are less serious disorders in which a person may experience such negative feelings as anxiety or depression. His functioning may be significantly impaired, but his personality remains relatively intact. he maintains a capacity for recognizing and objectively evaluating reality, and he is basically able to function in everyday life. In contrast to a person with a psychosis, an individual with a neurosis knows or can be made to realize that he is ill, and he usually wants to get well and return to a normal state. His chances for recovery are better than those of someone with a psychosis. The symptoms of neurosis may sometimes resemble the coping mechanisms used in everyday life by most people, but in persons with a neurosis these defensive reactions are inappropriately severe or prolonged in response to an external stress. Anxiety disorders, phobic disorder, conversion disorder, obsessive-compulsive disorder, and depressive disorders have been traditionally classified as neuroses.

Responsiveness of neuroses to therapy

Epidemiology. Epidemiology is the study of the distribution of disease in different populations. Prevalence denotes the number of cases of a condition present at a particular time or over a specified period, while incidence denotes the number of new cases occurring in a defined time period. Epidemiology is also concerned with the social, economic, or other contexts in which mental illnesses arise.

The understanding of mental disorders is aided by knowledge of the rate and frequency with which they occur in different societies and cultures. Looking at the worldwide prevalence of mental disorders reveals many surprising findings. It is remarkable, for instance, how constant the rate of developing schizophrenia is; in widely different cultures there is a lifetime risk of developing the illness of approximately just under 1 percent.

Gradual historical changes in the incidence and prevalence of particular disorders have often been described, but it is very difficult to obtain firm evidence that such changes have actually occurred. On the other hand, prevalence has been seen to increase for a few syndromes owing to general changes in living conditions over time. For example, dementia inevitably develops in some 20 percent of those persons over age 80, so that with the increase in life expectancy common to developed countries the number of people with dementia is bound to increase. Other factors, such as the presence of small quantities of aluminum in drinking water, may also play a part in the increased prevalence of dementia. There also seems to be some evidence of an increased prevalence of mood disorders over the past century.

Several large-scale epidemiological studies have been

conducted to determine the incidence and prevalence of mental disorders in the general population. Simple statistics based on those people actually under treatment for mental disorders cannot be relied upon in making such a determination because the number of those who have sought treatment is substantially smaller than the actual number of people afflicted with mental disorders, many of whom do not seek professional treatment. Moreover, surveys to determine incidence and prevalence depend for their statistics on the clinical judgment of the survey takers, which can always be fallible because there are no objective tests for the assessment of mental illness. Given such objections, one ambitious study conducted by the National Institutes of Mental Health in the United States examined thousands of persons in several American localities and yielded the following results concerning the prevalence of mental disorders in the general population. About 1.1 percent of those surveyed were found to have schizophrenia; 9.5 percent had depression; and 13.3 percent had phobias or other anxiety disorders.

Prevalence of mental disorders

There is a relatively strong epidemiological association between socioeconomic class and the occurrence of certain types of mental disorders and of general patterns of mental health. One study found that the lower the socioeconomic class, the greater the prevalence of psychotic disorders; schizophrenia was found to be 11 times more frequent among the lowest of the five classes surveyed (unskilled manual workers) than among the highest class (professionals). (Anxiety disorders were found to be more common among the middle class, however.) Two possible explanations for the elevated frequency of schizophrenia among the poor would be that persons with schizophrenia "drift downward" to the lowest socioeconomic class because they are impaired by their illness, or alternatively that unfavourable sociocultural conditions create circumstances that help induce the illness.

The manifestation of particular psychiatric symptoms is sometimes closely associated with particular epochs or periods in life. The symptoms of autism are usually evident by early childhood, for example. Childhood and adolescence may produce a variety of psychiatric symptoms peculiar to those periods of life. Anorexia nervosa, several types of schizophrenia, drug abuse, and bipolar disorder often first appear during adolescence or in young adult life. Alcohol dependence and its consequences, paranoid schizophrenia, and repeated attacks of depression are more likely to occur in middle age. Involutional melancholia and presenile dementias typically occur in late middle age, while senile and arteriosclerotic dementias are characteristic of the elderly.

There are also marked sex differences in the incidence of certain types of mental illness. For instance, anorexia nervosa is 20 times more common in girls than boys; men tend to develop schizophrenia at a younger age than women; depression is more common in women than men; and many sexual deviations occur almost exclusively in men.

THEORIES OF CAUSATION

Very often the etiology, or cause, of a particular type of mental disorder is unknown or is understood only to a very limited extent. The situation is complicated by the fact that a mental disorder such as schizophrenia may be caused by a combination and interaction of several factors, including a probable genetic predisposition to developing the disease, a postulated biochemical imbalance in the brain, and a cluster of stressful life events that help to precipitate the actual onset of the illness. The predominance of these and other factors probably varies from person to person in schizophrenia. A similarly complex interaction of constitutional, developmental, and social factors can influence the formation of mood and anxiety disorders.

No single theory of causation can explain all mental disorders or even all those of a particular type, and, moreover, the same type of disorder may have different causes in different persons; *e.g.*, an obsessive-compulsive disorder may have its origins in a biochemical imbalance, in an unconscious emotional conflict, in faulty learning processes, or in a combination of these. The fact that quite different therapeutic approaches can produce equal improvements in different patients with the same type of disorder underscores the complex and ambiguous nature of the causes of mental illness. The major theoretical and research approaches to the causation of mental disorders are treated below.

Organic and hereditary etiologies. Organic explanations of mental illness have usually been genetic, biochemical, neuropathological, or a combination of these.

Genetics. The study of the genetic causes of mental disorders involves both the laboratory analysis of the human genome and the statistical analysis of the frequency of a particular disorder's occurrence among individuals who share related genes—*i.e.*, family members and particularly twins. Family-risk studies compare the observed frequency of occurrence of a mental illness in close relatives of the patient with its frequency in the general population. First-degree relatives (parents, siblings, and children) share 50 percent of their genetic material with the patient, and higher rates of the illness in these relatives than expected indicate a possible genetic factor. In twin studies the frequency of occurrence of the illness in both members of pairs of identical (monozygotic) twins is compared with its frequency in both members of a pair of fraternal (dizygotic) twins. A higher concordance for disease among the identical than the fraternal twins suggests a genetic component. Further information on the relative importance of genetic and environmental factors accrues from comparing identical twins reared together with those reared apart. Adoption studies comparing adopted children whose biological parents had the illness with those whose parents did not can also be useful in separating biological from environmental influences.

Genetic predisposition to mental disorders

Such studies have demonstrated a clear role for genetic factors in the causation of schizophrenia. When one parent is found to have the disorder, the probability that his children will develop schizophrenia is at least 10 times higher (about a 12 percent risk probability) than it is for children in the general population (about a 1 percent risk probability). If both parents have schizophrenia, their children stand anywhere from a 35 to a 65 percent probability of developing schizophrenia. If one member of a pair of fraternal twins develops schizophrenia, there is about a 12 percent chance that the other twin will also develop the disorder. If one member of a pair of identical twins has schizophrenia, the other identical twin has at least a 40–50 percent chance of developing the disease. Genetic factors seem to play a less significant role in the causation of other psychotic disorders and in personality disorders. However, studies have demonstrated a probable role for genetic factors in the causation of many mood disorders and some anxiety disorders.

Biochemistry. If a mental disease is caused by a biochemical abnormality, investigation of the brain at the site where the biochemical imbalance occurs should show neurochemical differences from normal. In practice such a simplistic approach is fraught with practical, methodological, and ethical difficulties. The living human brain is not readily accessible to direct investigation, and the dead brain undergoes chemical change; moreover, findings of abnormalities in cerebrospinal fluid, blood, or urine may have no relevance to the question of a presumed biochemical imbalance in the brain. It is difficult to study human mental illnesses by using animals as analogs, because most mental disorders either do not occur or are not recognizable in animals. Even when biochemical abnormalities have been found in persons with mental disorders, it is difficult to know whether such abnormalities are the cause or the result of the illness, of its treatment, or of other consequences. Despite these problems, progress has been made in unraveling the biochemistry of mood disorders, schizophrenia, and some of the dementias.

Certain drugs have been demonstrated to have beneficial effects upon mental illnesses. Antidepressant, antipsychotic, and antianxiety drugs are thought to achieve their therapeutic results by the selective inhibition or enhancement of the quantities, action, or breakdown of neurotransmitters in the brain. Neurotransmitters are a group of chemical agents that are released by neurons (nerve cells) to stimulate neighbouring neurons, which thus allows im-

Role of neurotransmitters

pulses to be passed from one cell to the next throughout the nervous system. Neurotransmitters play a key role in transmitting nerve impulses across the microscopic gap (synaptic cleft) that exists between neurons. The release of such neurotransmitters is stimulated by the electrical activity of the cell. Norepinephrine, dopamine, acetylcholine, and serotonin are among the principal neurotransmitters. Some neurotransmitters excite or activate neurons, while others act as inhibiting substances. Abnormally low or high concentrations of neurotransmitters at sites in the brain are thought to change the synaptic activities of neurons and thus ultimately lead to the disturbances of mood, emotion, or thought found in various mental disorders.

Neuropathology. In the past the pathological study of the brain at postmortem revealed information upon which great advances in understanding of the etiology of neurological and some mental disorders were based, which led to the German psychiatrist Wilhelm Griesinger's postulate: "All mental illness is disease of the brain." The application of the principles of pathology to general paresis of the insane, one of the most common conditions found in mental hospitals in the late 19th century, resulted in the discovery that this was a form of neurosyphilis and was caused by infection with the spirochete bacterium *Treponema pallidum.* The examination of the brains of patients with other forms of dementia has given useful information concerning other causes of this syndrome—for example, Alzheimer's disease and arteriosclerosis. The pinpointing of abnormalities of specific areas of the brain has aided understanding of some abnormal mental functions, such as disturbances of memory or speech disorders. Recent advances in neuroimaging techniques have expanded the ability to investigate brain abnormalities in patients with a wide variety of mental illnesses and no longer require that these studies occur postmortem.

Psychodynamic etiologies. Up to the 1950s theories of the etiology of mental disorders, especially of neuroses and personality disorders, were dominated in the United States by Freudian psychoanalysis and the derivative theories of the post-Freudians. In western Europe the influence of Freudian theory upon psychiatric theory diminished after World War II.

Theories of personality development. Freudian and other psychodynamic theories view neurotic symptoms as arising from intrapsychic conflict—that is, as being caused by conflicting motives, drives, impulses, and feelings held within various components of the mind. Central to psychoanalytic theory is the postulated existence of the unconscious, which is that part of the mind whose processes and functions are inaccessible to the individual's conscious awareness or scrutiny. One of the functions of the unconscious is thought to be that of a repository for traumatic memories, feelings, ideas, wishes, and drives that are threatening, abhorrent, anxiety-provoking, or socially or ethically unacceptable to the individual. These mental contents may at some time be pushed out of conscious awareness but remain actively held in the unconscious. This process is a defense mechanism for protecting the individual from the anxiety or other psychic pain associated with those contents and is known as repression. The repressed mental contents held in the unconscious retain much of the psychic energy or power that was originally attached to them, however, and they can continue to influence significantly the mental life of the individual even though (or because) he is no longer aware of them.

The natural tendency for repressed drives or feelings, according to this theory, is to break through into conscious awareness so that the individual can seek the gratification, fulfillment, or resolution of them. But this threatened release of forbidden impulses or memories provokes anxiety and is seen as threatening, and a variety of defense mechanisms may then come into play to provide relief from the state of psychic conflict. Through reaction formation, projection, regression, sublimation, rationalization, and other defense mechanisms, some component of the unwelcome mental contents can emerge into consciousness in a disguised or attenuated form and thus provide partial relief to the individual. Later, perhaps in adult life, some event or situation in the person's life triggers the abnormal discharge of the dammed-up or strangulated emotional energy in the form of neurotic symptoms in a manner mediated by defense mechanisms. Such symptoms can form the basis of neurotic disorders such as conversion and somatoform disorders, anxiety disorders, obsessional disorders, and depressive disorders. Since the symptoms represent a compromise within the mind between letting the repressed mental contents out and continuing to deny all conscious knowledge of them, the particular character and aspects of an individual's symptoms and neurotic concerns bear an inner meaning that symbolically represents the underlying intrapsychic conflict. Psychoanalysis and other dynamic therapies associate the patient's controlled and therapeutic recovery to conscious awareness of repressed mental conflicts, and his understanding of their influence on both his past history and his present difficulties, with the relief of symptoms and improved mental functioning.

Childhood experience and neurosis

Freudian theory views childhood as the primary breeding ground of neurotic conflicts. This is because children are relatively helpless and are dependent on their parents for love, care, security, and support and because their psychosexual, aggressive, and other impulses are not yet integrated into a stable personality framework. Children are thus subject to emotional traumas, deprivations, and frustrations which they lack the resources to cope with and which can become grounds for intrapsychic conflicts that are not resolved but rather merely held in abeyance through repression, producing insecurity, unease, or guilt and subtly influencing the individual's developing personality, interests, attitudes, and ability to cope with later stresses.

Non-Freudian psychodynamics. Psychoanalytic theory's emphasis on the unconscious mind and its influence on human behaviour resulted in a proliferation of other, related theories of causation incorporating many basic psychoanalytic precepts. Most subsequent psychotherapies have stressed in their theories of causation aspects of earlier, maladaptive psychological development that had been missed or underemphasized by orthodox psychoanalysis, or they have incorporated insights taken from learning theory. The Swiss psychiatrist Carl Jung, for instance, concentrated on the individual's need for spiritual development and concluded that neurotic symptoms could arise from a lack of self-fulfillment in this regard. The Austrian psychiatrist Alfred Adler emphasized the importance of feelings of inferiority and the unsatisfactory attempts to compensate for it as important causes of neurosis. Neo-Freudian authorities such as Harry Stack Sullivan, Karen Horney, and Erich Fromm modified Freudian theory by emphasizing social relationships and cultural and environmental factors as being important in the formation of mental disorders. Many other highly specific theories of causation have been developed by particular psychotherapies, and, in general, psychiatric scrutiny has come to extend far beyond the confines of early psychosexual development that were originally posited by Freud as the prime ground for the causation of neuroses. More modern psychodynamic theories have moved away from the idea of explaining and treating neurosis on the basis of a defect in a single psychological system and have instead adopted a more complex notion of multiple causes, including emotional, psychosexual, social, cultural, and existential ones. A notable trend in the more recently developed psychotherapies has been the incorporation of approaches derived from theories of learning. Such psychotherapies pay special attention to acquired faulty mental processes and maladaptive behavioral responses that act to sustain neurotic symptoms, and there has generally been increased interest in the patient's present circumstances and his learned responses to those conditions as a causative factor in mental illness. In this way, psychoanalytic theory and behavioral theory have tended somewhat to converge and intermingle in their views of disease causation.

Behavioral etiology. Behavioral theories for the causation of mental disorders, especially neurotic symptoms, are based upon learning theory, which was in turn largely derived from the study of the behaviour of animals in laboratory settings. Most important theories in this area arose out of the work of the Russian physiologist Ivan Pavlov and such American psychologists as Edward L. Thorndike,

Clark L. Hull, John B. Watson, Edward C. Tolman, and B.F. Skinner. In the classical Pavlovian model of conditioning, an unconditioned stimulus is followed by an appropriate response; for example, food placed in a dog's mouth is followed by the dog's salivating. If a bell is rung just before food is offered to a dog, eventually the dog will salivate at the sound of the bell only, even though no food is offered. Because the bell could not originally evoke salivation in the dog (and hence was a neutral stimulus) but came to evoke salivation because it was repeatedly paired with the offering of food, it is called a conditioned stimulus. The dog's salivation at the sound of the bell alone is called a conditioned response. If the conditioned stimulus (the bell) is no longer paired with the unconditioned stimulus (the food), extinction of the conditioned response gradually occurs (the dog ceases to salivate at the sound of the bell alone).

Behavioral theories for the causation of mental disorders rest largely upon the assumption that the symptoms or symptomatic behaviour found in persons with various neuroses (particularly phobias and other anxiety disorders) can be regarded as learned behaviours that have been built up into conditioned responses. In the case of phobias, for example, a person who has once been exposed to an inherently frightening situation afterward experiences anxiety even at neutral objects that were merely associated with that situation at the time but that should not reasonably produce anxiety; *e.g.*, a child who has had a frightful experience with a bird may subsequently have an unreasonable dread of feathers. The neutral object alone is enough to arouse anxiety, and the person's subsequent effort to avoid that object is a learned behavioral response that is self-reinforcing, since the person does indeed procure a reduction of his anxiety by avoiding the feared object and is thus likely to continue to avoid it in the future. It is only by confronting the object that he can eventually lose his irrational association-based fear of it.

The role of conditioned responses

Other etiologies. Mental illness may be contagious in a psychological sense; that is, close contact with an individual who has symptoms may result in the transmission of those symptoms to one or many others who were previously unaffected. This may occur either through the powerful influence of long-term cohabitation of one person with one other—a phenomenon known as folie à deux—or through the volatile collective emotions of a group—mass hysteria.

Social values can sometimes determine or encourage the formation of particular syndromes. Prime examples of this are anorexia nervosa and bulimia nervosa, which predominantly affect young white females in affluent Western societies. The value and attractiveness of physical thinness are communicated via the media, and an eating disorder resulting in emaciation subsequently occurs in some susceptible individuals.

Another approach to the causation of mental disorders focuses on the effects and consequences of stress, which is a state of bodily or mental tension resulting from external factors such as marital conflicts, excessive work demands, or serious financial problems. Stress may cause psychosomatic illnesses or an exacerbation or worsening of real somatic illnesses. An accumulation of stressful life events can contribute to the development of depression in psychologically vulnerable individuals.

MAJOR DIAGNOSTIC CATEGORIES

Organic mental disorders. This category includes both those psychological or behavioral abnormalities that arise from structural disease of the brain and those that arise from brain dysfunction caused by disease outside the brain. These conditions differ from those of other mental illnesses in that they have a definite and ascertainable cause—*i.e.*, brain disease. However, the importance of the distinction (between organic and functional) has become less clear as research has demonstrated that brain abnormalities are associated with many psychiatric illnesses. Treatment, when possible, is aimed at both the symptoms and the underlying physical dysfunction in the brain.

There are several types of psychiatric syndromes that arise clearly from organic brain disease, chief among them being dementia and delirium. Dementia is a gradual and progressive loss of such intellectual abilities as thinking, remembering, paying attention, judging, and perceiving, without an accompanying disturbance of consciousness. The syndrome may also be marked by the onset of personality changes. Dementia is usually a chronic condition and frequently worsens over the long term. Delirium is a diffuse or generalized intellectual impairment marked by a clouded or confused state of consciousness, an inability to attend to one's surroundings, difficulty in thinking coherently, a tendency to perceptual disturbances such as hallucinations, and difficulty in sleeping. Delirium is generally an acute condition. Amnesia (*i.e.*, a gross loss of recent memory and time sense without other intellectual impairment) is another specific psychological impairment associated with organic brain disease.

In the diagnosis of suspected organic disorders, a full history must first be taken of the patient and his mental state must be examined in detail, with additional tests for particular functions added if necessary. A physical examination is also performed with special attention to the central nervous system. In order to determine whether a metabolic or other biochemical imbalance is causing the condition, blood and urine tests, liver function tests, thyroid function tests, and other evaluations may be performed. Chest and skull X rays may be taken, and computed tomography (CT) scanning or magnetic resonance imaging (MRI) is frequently used to reveal focal or generalized brain disease. Electroencephalography (EEG) may show localized abnormalities in the electrical conduction of the brain caused by a lesion. Detailed psychological testing may reveal more specific perceptual, memory, or other disabilities.

Senile and presenile dementia. In these dementias there is a progressive intellectual impairment that proceeds to lethargy, inactivity, and gross physical deterioration and eventually to death within a few years. Presenile dementias are arbitrarily defined as those that begin in persons under the age of 65. In old age the most common causes of dementia are Alzheimer's disease and cerebral arteriosclerosis. Dementia from Alzheimer's disease usually begins in people over age 65 and is more common in women than in men. It begins with incidences of forgetfulness, which become more frequent and serious, and the disturbances of memory, personality, and mood progress steadily toward physical deterioration and death within a few years. In dementia caused by cerebral arteriosclerosis, multiple areas of destruction of the brain (infarcts) are caused by pieces of the damaged arteries outside the skull lodging in the small arteries of the brain. The course of the illness is rapid, with periods of deterioration followed by periods of slight improvement. Death may be delayed slightly longer than with dementia from Alzheimer's disease and often occurs from ischemic heart disease, causing a heart attack, or from massive cerebral infarction, causing a stroke.

Alzheimer's disease

Other causes of dementia include Pick's disease, a rare inherited condition that occurs in women twice as often as men, usually between the ages of 50 and 60; Huntington's chorea, an inherited disease that usually begins at about the age of 40 with involuntary movements and proceeds to dementia and death within 15 years; and Creutzfeldt-Jakob disease, a rare condition that is caused by an abnormal protein found in the brain called a prion. Head injury—for instance, resulting from a boxing career or from an accident—may produce dementia. Infection—for example, with syphilis or encephalitis—various tumours, toxic conditions such as chronic alcoholism or heavy metal poisoning, metabolic illnesses such as liver failure, reduced oxygen to the brain due to anemia or carbon monoxide poisoning, and the inadequate intake or metabolism of certain vitamins may all result in dementia.

There is no specific treatment for the symptoms of dementia; the underlying physical cause needs to be identified and treated when possible. The goals of care of the individual with dementia are to relieve distress, prevent behaviour that might result in injury, and optimize remaining physical and psychological faculties.

Substance-induced disorders. A variety of psychiatric conditions can result from the use of alcohol or other drugs. Mental disorders resulting from the ingestion of al-

cohol include intoxication, withdrawal, hallucinations, and amnesia. Similar syndromes may occur following the use of other drugs that affect the central nervous system (see ALCOHOL AND DRUG CONSUMPTION). Those drugs most commonly used recreationally to alter mood are barbiturates, opioids (*e.g.,* heroin), cocaine, amphetamines, hallucinogens such as LSD (lysergic acid diethylamide), marijuana, and tobacco. Treatment is directed at alleviating symptoms and preventing further abuse of the substance. Substance abuse implies a sustained pattern of use, resulting in an impairment of the individual's daily functioning. Substance dependence occurs when the individual who is abusing a substance becomes physically tolerant of it; in other words, he must administer markedly increased amounts of the drug to achieve the same effect that would have previously occurred with smaller doses. Dependence is also characterized by withdrawal symptoms, which may include tremors, nausea, and anxiety, that follow the cessation of drug use or decreases in dosage.

Schizophrenia. The term *schizophrenia* was introduced by Swiss psychiatrist Eugen Bleuler in 1911 to describe what he considered to be a group of severe mental illnesses with related characteristics; *schizophrenia* eventually replaced the earlier term *dementia praecox,* which the German psychiatrist Emil Kraepelin had first used in 1899 to distinguish the disease from what is now called bipolar disorder. Individuals with schizophrenia exhibit a wide variety of symptoms; thus, although different experts may agree as to whether a particular individual suffers from the condition, they might disagree about which symptoms are essential in clinically defining schizophrenia.

The annual prevalence of schizophrenia—that is, the number of cases both old and new recorded in one year—is between two and four per 1,000 persons. The lifetime risk of developing the illness is between seven and nine per 1,000. Schizophrenia is the single largest cause of admissions to mental hospitals, and it accounts for an even larger proportion of the permanent populations of such institutions. It is a severe and frequently chronic illness that typically first manifests itself during the teen years or during early adult life. More severe levels of impairment and personality disorganization occur in schizophrenia than in almost any other mental disorder.

Clinical features. The principal clinical signs of schizophrenia are delusions, hallucinations, a loosening or incoherence of a person's thought processes and train of associations, deficiencies in feeling appropriate or normal emotions, and a withdrawal from reality. A delusion is a false or irrational belief that is firmly held despite obvious or objective evidence to the contrary. The delusions of individuals with schizophrenia may be persecutory, grandiose, religious, sexual, or hypochondriacal in nature, or they may be concerned with other topics. Delusions of reference, in which the person attributes a special, irrational, and usually negative significance to other people, objects, or events, are common in the disease. Especially characteristic of schizophrenia are delusions in which the individual believes his thinking processes, body parts, or actions or impulses are controlled or dictated by some external force.

Hallucinations in schizophrenia

Hallucinations are false sensory perceptions that are experienced without an external stimulus but that nevertheless seem real to the person who is experiencing them. Auditory hallucinations, experienced as "voices" and characteristically heard commenting negatively about the affected person in the third person, are prominent in schizophrenia. Hallucinations of touch, taste, smell, and bodily sensation may also occur. Disorders of thinking vary in nature but are quite common in schizophrenia. Thought disorders may consist of a loosening of associations, so that the speaker jumps from one idea or topic to another unrelated one in an illogical, inappropriate, or disorganized way. At its most serious, this incoherence of thought extends into pronunciation itself, and the speaker's words become garbled or unrecognizable. Speech may also be overly concrete and inexpressive; it may be repetitive, or, though voluble, it may convey little or no real information. Usually an individual with schizophrenia has little or no insight into his own condition and realizes neither that he is suffering from a mental illness nor that his thinking is disordered.

Among the so-called negative symptoms of schizophrenia are a blunting or flattening of the person's ability to experience (or at least to express) emotion, indicated by speaking in a monotone and by a peculiar lack of facial expressions. The person's sense of self (*i.e.,* of who he is) may be disturbed. A person with schizophrenia may be apathetic and may lack the drive and ability to pursue a course of action to its logical conclusion, may withdraw from society, may become detached from others, or may become preoccupied with bizarre or nonsensical fantasies. Such symptoms are more typical of chronic rather than of acute schizophrenia.

Major types of schizophrenia

Experts have recognized many different types of schizophrenia, and there are intermediate stages between the disease and other conditions. Five major types of schizophrenia are recognized by the DSM-IV: the disorganized type, the catatonic type, the paranoid type, the undifferentiated type, and the residual type. Disorganized schizophrenia is characterized by inappropriate emotional responses and by incoherent thought and speech. Catatonic schizophrenia is marked by striking motor behaviour, such as remaining motionless in a rigid posture for hours or even days, and by stupor or mutism. Paranoid schizophrenia is characterized by the presence of prominent delusions of a persecutory or grandiose nature. The undifferentiated and residual types are marked by the absence of these distinct features; the residual type is, moreover, a less severe diagnosis.

Course and prognosis. The course of schizophrenia is variable. Some individuals with schizophrenia continue to function fairly well and are able to live independently; some have recurrent episodes of the illness with some negative effect on their overall level of function; and some deteriorate into chronic schizophrenia with severe disability. The prognosis for individuals with schizophrenia has improved owing to the use of antipsychotic drugs and community supportive measures.

About 10 percent of individuals with schizophrenia commit suicide. The prognosis of schizophrenia is poorer when it has a gradual rather than a sudden onset, when the affected individual is quite young at the onset of the disease, when there is a long duration of illness, when the individual exhibits blunted feelings or has displayed an abnormal personality previous to the onset of the disease, and when such social factors as never having been married, poor sexual adjustment, a poor employment record, or social isolation exist in the person's history.

Etiology. An enormous amount of research has been performed to try to determine the causes of schizophrenia. Family, twin, and adoption studies provide strong evidence to support an important genetic contribution. A recent study found that children born to men who are over the age of 50 are nearly three times more likely to have schizophrenia than those born to younger men. Stressful life events are known to trigger or quicken the onset of schizophrenia or to cause relapse. Some abnormal neurological signs have been found in individuals with schizophrenia, and it is possible that brain damage, perhaps occurring at birth, may be a cause in some cases. Other studies hypothesize that the cause of schizophrenia is linked to a virus or to the abnormal activity of genes governing the formation of nerve fibres in the brain. Various biochemical abnormalities have been reported in persons with schizophrenia. There is evidence that the abnormal coordination of neurotransmitters such as dopamine, glutamate, and serotonin may be involved in the development of the disease. The neurodevelopmental model currently best incorporates how biological and environmental influences affect the onset and progression of schizophrenia. Functional neuroimaging studies have demonstrated that the frontal and limbic areas of the brain are abnormal in persons with schizophrenia.

Research also has been performed to determine whether the prenatal care used in the families of individuals with schizophrenia contributes to the development of the disease. There has also been extensive interest in such factors as social class, place of residence, migration, and social

isolation. Neither family dynamics nor social disadvantage has been proved to be a causative agent.

Treatment. The most successful treatment approaches combine the use of medications and supportive therapy. New "atypical" antipsychotic medications such as clozapine, risperidone, and olanzapine have proved effective in relieving or eliminating such symptoms as delusions, hallucinations, thought disorders, agitation, and violent behaviour. These medications also have fewer side effects than the more traditional antipsychotic medications. Long-term maintenance on such medications also reduces the rate of relapse. Psychotherapy may help relieve feelings of helplessness and isolation, reinforce healthy or positive tendencies, allow the affected individual to distinguish between his psychotic perceptions and reality, and explore any underlying emotional conflicts that might be exacerbating the condition. Occupational therapy and regular visits from a social worker or psychiatric nurse may be beneficial. It is sometimes useful to counsel the relatives of individuals with schizophrenia living at home. Support groups for persons with schizophrenia and their family members have become extremely important resources for dealing with the disorder.

Paranoid disorders. Paranoia is a syndrome in which a person thinks or believes, without justification, that other people are plotting or conspiring against, persecuting, harming, or harassing him in some way. Paranoid thinking frequently causes a person to interpret or exaggerate innocuous or trivial incidents in a self-referent way—*e.g.,* to see two people talking at a distance and to assume irrationally that they are plotting against or criticizing him. Grandiosity or delusions of grandeur, which consist of exaggerated and unjustified ideas of a person's own importance, wealth, or power, frequently coexist with the classic persecutory orientation in paranoia. Paranoia or paranoid thinking can be a prominent or primary feature in schizophrenia (paranoid schizophrenia), personality disorders, senile dementias, mood disorders, and bipolar disorder. Persons with paranoid disorder are usually otherwise normal people who may be simply abnormally suspicious, or they may have an unshakable and highly elaborate delusional system involving worldwide conspiracies against them. A special type of paranoia is delusional jealousy, in which a person delusionally believes or suspects that his spouse is having sexual relations with someone else. A paranoid disorder can seriously impair an individual's social or marital functioning, but the remainder of his thinking remains clear and orderly, his intellectual functioning is impaired only minimally or not at all, and the core of his personality remains intact. The treatment of persons with paranoid disorders involves the use of antipsychotic medications, frequently on a long-term-maintenance basis.

Mood disorders. These disorders are usually restricted to just two abnormalities of mood—depression and elation, or mania.

Depression is characterized by a sad or hopeless mood, pessimistic thinking, a loss of enjoyment and interest in one's usual activities and pastimes, reduced energy and vitality, increased fatigue, slowness of thought and action, change of appetite, and disturbed sleep. Depression must be distinguished from the grief and low spirits felt in reaction to the death of a loved one or some other unfortunate circumstance. The most dangerous consequence of severe depression is suicide.

Mania is characterized by an elated or euphoric mood, quickened thought and accelerated, loud, or voluble speech, overoptimism and heightened enthusiasm and confidence, inflated self-esteem, heightened motor activity, irritability, excitement, and a decreased need for sleep. The manic individual may injure himself, commit illegal acts, or suffer financial losses due to the poor judgment and risk-taking behaviour he displays when in the manic state.

Major mood disorders. The DSM-IV defines two major, or severe, mood disorders: bipolar disorder and major depression. A person with bipolar disorder, previously known as manic-depressive disorder, typically experiences discrete episodes of depression and then of mania lasting for a few weeks or months, with intervening periods of complete normality. The sequence of depression and mania can vary widely from person to person and within one individual, with either mood abnormality predominating in duration and intensity. Depressive mood swings typically occur more often and last longer than manic ones, though there are persons who have episodes only of mania. Individuals with bipolar disorder frequently also show psychotic symptoms such as delusions, hallucinations, paranoia, or grossly bizarre behaviour.

Bipolar disorder

The lifetime risk of developing bipolar disorder is about 1 percent and is about the same for men and women. The onset of the illness often occurs around the age of 30, and the illness persists over the long term. The predisposition to developing bipolar disorder is partly genetically inherited. Antipsychotic medications are used for the treatment of acute or psychotic mania. Mood-stabilizing agents such as lithium and several antiepileptic medications have proved effective in both treating and preventing recurrent attacks of mania.

Severe and long-lasting depression without the presence of mania is classified by the DSM-IV as major depressive disorder. Depression is a much more common illness than mania, and there are indeed many sufferers from depression who have never experienced mania. Major depressive disorder may occur as a single episode, or it may be recurrent. It may also exist with or without melancholia and with or without psychotic features. Melancholia implies the biological symptoms of depression: early-morning waking; daily variations of mood with depression most severe in the morning; loss of appetite and weight; constipation; and loss of interest in love and sex. Melancholia is a particular depressive syndrome that is relatively more responsive to somatic treatments such as medications (*e.g.,* Prozac, Paxil, and Zoloft) and electroconvulsive therapy (ECT).

Depression

It is estimated that women experience depression about twice as often as men. While the rates for major depression in men increase with age, the peak for women is between the ages of 35 and 45. There is a serious risk of suicide with the illness; of those who have a severe depressive disorder, about one-sixth eventually kill themselves. The loss of one's parents while a child or other childhood traumas or deprivations can increase a person's vulnerability to depression later in life, and stressful life events, especially where some type of loss is involved, are, in general, potent precipitating causes of the illness. It seems that both psychosocial and biochemical mechanisms are important in causing depression. Of the latter factor, the best-supported hypotheses suggest that the faulty regulation of the release of one or more neurotransmitters (*e.g.,* serotonin, dopamine, and norepinephrine) where the transmission of nerve impulses takes place is the basic cause, with a deficiency of the neurotransmitters resulting in depression and an excess causing mania. The treatment of major depressive episodes usually requires antidepressant medications. Electroconvulsive therapy may also be helpful, as may cognitive, behavioral, and interpersonal psychotherapies.

Additional mood disorders. A less severe manifestation of bipolar disorder, in which the mood swings are present but not as extreme, is termed cyclothymic disorder. The prevailing mood swings are established in adolescence and continue throughout adult life.

Dysthymic disorder, or depressive neurosis, may occur on its own, but it more commonly appears along with other neurotic symptoms such as anxiety, phobia, and hypochondriasis. Where there are clear external grounds for a person's unhappiness, a dysthymic disorder is considered to be present when the depressed mood is disproportionately severe or prolonged in regard to the distressing experience, when there is a preoccupation with the precipitating situation, when the depression continues even after removal of the provocation, and when it impairs the individual's ability to cope with the specific stress.

At any time, depressive symptoms may be present in one-sixth of the population, more commonly in women than men. Loss of self-esteem, feelings of helplessness and hopelessness, and loss of cherished possessions are also seen as important causes of minor depression. Psychotherapy is the treatment of choice for both dysthymic disorder and cyclothymic disorder, although antidepressant medications

or mood-stabilizing agents are often beneficial. Symptoms must be present for at least two years in order for a diagnosis of dysthymic or cyclothymic disorder to be made.

Anxiety disorders. Anxiety is defined as a feeling of fear, dread, or apprehension that arises without a clear or appropriate justification. Some experts differentiate anxiety from true fear in that the latter is experienced in response to an actual threat or danger, such as those to one's physical safety. Anxiety, on the other hand, may arise in response to apparently innocuous situations or may be out of proportion to the actual degree of the external stress. Anxiety also frequently arises as a result of subjective emotional conflicts of whose nature the person himself may be unaware. Generally, intense, persistent, or chronic anxiety that is not justified in response to real-life stresses and that interferes with the individual's functioning is regarded as a manifestation of mental disorder. Anxiety is a symptom of many mental disorders, including schizophrenia, obsessive-compulsive disorders, posttraumatic stress disorders, and so on, but, in phobias and other anxiety disorders proper, anxiety is the primary and frequently the only symptom.

The symptoms of anxiety are physical, psychological, and behavioral. Anxiety, especially during panic attacks, can manifest itself in a distinctive set of physical signs that arise from overactivity of the sympathetic nervous system or from tension in skeletal muscles. The sufferer experiences palpitations, dry mouth, dilation of the pupils, shortness of breath, sweating, abdominal symptoms, tightness in the throat, trembling, and dizziness. Aside from the actual feelings of dread and apprehension, the psychological symptoms include irritability, difficulty concentrating, and restlessness. Anxiety may also be manifested in avoidance behaviour (*e.g.,* running away from the feared object or situation).

Phobic disorder. Phobias are neurotic states accompanied by intense dread of certain objects or situations that would not normally have such an effect. This type of anxiety is associated with a strong desire to avoid the dreaded object or situation. About 6 per 1,000 of the population suffer from a phobic disorder. There is a tendency for phobic symptoms, whatever their nature, to persist for many years unless treated, and the avoidance behaviour they produce can seriously limit the affected individual's movements and his social or occupational functioning.

People can have phobias about many different kinds of objects or situations, but three main divisions of phobic syndromes are made by the DSM-IV: specific phobia, agoraphobia, and social phobia. Individuals with specific phobias may intensely fear a specific object or situation—for example, cats or thunderstorms. They have anxious thoughts upon anticipating contact with an object or event—for instance, upon hearing the weather forecast—and they try to avoid the object, as in staying indoors in order not to encounter a cat. Typically, individuals with agoraphobia have an intense fear of being alone in or being unable to escape from a public place or some other setting outside the home, such as a crowded bus or a supermarket. A social phobia is present when individuals have extreme anxiety in a social situation where they are under the scrutiny of others, such as eating in a restaurant or speaking at a meeting.

Agoraphobia

The treatment of phobic disorders is best approached by the use of behavioral therapy. Dynamic psychotherapy and antianxiety medications may be effective in some cases.

Panic disorder and generalized anxiety disorder. Anxiety disorders in which the anxiety is not aroused by any specific object or situation can basically be subsumed under the headings of panic disorder and generalized anxiety disorder. Panic attacks are characterized by the sudden onset of intense or overwhelming anxiety accompanied by any of the aforementioned physical signs, such as difficulty in breathing, sweating, palpitations, and so on. The fear and apprehension experienced in such attacks sometimes mount to what are known as feelings of doom. Clear precipitating circumstances may produce the initial feelings of intense anxiety. The panic attack may last for about 15 minutes and often recurs, either infrequently or several times a week. The disorder usually starts in young adulthood and may persist for many years.

A diffuse and persistent feeling of anxiety associated with no particular object or situation is termed general, or free-floating, anxiety and is classified by the DSM-IV as generalized anxiety disorder. General anxiety is usually milder and less intense than in panic attacks, but it is longer-lasting and may persist for several months or years or on a recurrent basis. The most effective treatments vary according to the type of disorder and the individual. Psychotherapy and antianxiety medications are often useful in treating generalized anxiety disorder and panic disorder.

Obsessive-compulsive disorder. In this condition an individual experiences obsessions or compulsions or both. Obsessions are recurring words, thoughts, ideas, or images that, rather than being experienced as voluntarily produced, seem to invade a person's consciousness despite his attempts to ignore, control, or suppress them. The obsessional thought or topic is perceived by the individual as inappropriate or senseless; the idea is recognized as both alien to his nature and yet as coming from inside himself. An obsession can take the form of a recurrent and vivid fantasy that is often obscene, disgusting, or senseless. The person with obsessional ruminations holds endless debates over mundane matters inside his head (*e.g.,* "Did I forget to lock the front door behind me?").

Obsessions in turn are frequently linked to compulsions. These are urges or impulses to perform repetitive acts that are apparently meaningless, unnecessary, stereotyped, or ritualistic. The compulsive person knows that the act to be performed is meaningless or unnecessary, but failure or refusal to perform it brings on a mounting tension or anxiety that is temporarily relieved once the act has been performed. Obsessional ruminations thus directly produce compulsive behaviour (*e.g.,* repeatedly checking and relocking an already secure front door). Most compulsive acts have a simple, ritualistic character and can involve checking, touching, hand washing, or the repetition of particular words or phrases.

Medications, psychotherapy, and behavioral therapy are selectively successful in treating obsessive-compulsive disorders, depending on the individual. An older medication, clomipramine, and newer selective serotonin reuptake inhibitor (SSRI) medications have proved effective in reducing the symptoms in a large proportion of individuals with obsessive-compulsive disorder.

Posttraumatic stress disorder. In this condition symptoms develop in an individual after he has experienced a psychologically traumatic event. It is a category in the DSM-IV classification but is not different in its symptomatology from other anxiety conditions; the distinctive feature is the presence of external trauma. The traumatic events can include serious automobile accidents, rape or assault, military combat, torture, incarceration in a concentration or death camp, and such natural disasters as floods, fires, and earthquakes.

A feature of this condition is the person's reexperiencing of the traumatic event in nightmares and in intrusive daytime fantasies. Increased arousal is common, with insignificant events, such as a knock at the door, precipitating a sudden terrifying recollection and an exaggerated startle response. Other symptoms include emotional numbing, avoidance of stimuli associated with the trauma, a diminished ability to enjoy activities or relationships that were previously pleasurable, and difficulty in sleeping. Long-term symptoms of distress, marital and family problems, difficulties at work, and the abuse of alcohol and other drugs are characteristic impairments caused by the disorder.

The marked emotional symptoms may persist long after the actual occurrence of the traumatic event. Some persons are more liable than others to develop the disorder, depending on personality traits, previous psychological disturbances, age, and genetic predisposition. Psychotherapy is the basic approach used in treating this disorder.

Somatoform disorders. In these conditions the physical symptoms of the person suggest the presence of organic disease, but no such organic disorder can be found upon physical examination and investigation, and instead there is evidence that the symptoms are caused by psychological factors. The production of these symptoms is not under

voluntary control. The terms *hypochondriasis* and *hysteria* were traditionally used to designate these disorders.

Physical pain caused by psychological conflict

Somatization disorder. This disorder was previously designated Briquet's syndrome; its essential features consist of multiple recurrent physical complaints made over many years and starting in young adult life or adolescence. The individual demands medical attention, but no organic cause is found. The symptoms invariably occur in many different bodily systems—for instance, back pains, dizziness, indigestion, difficulty with vision, and partial paralysis—and the symptoms may follow trends in health concerns among the public.

The condition is relatively common and occurs in about 1 percent of adult women. Males rarely exhibit this disorder. There are no clear etiological factors. Treatment involves not agreeing with the person's inclination to attribute organic causes to the symptoms and ensuring that physicians and surgeons do not cooperate with the person in seeking excessive diagnostic procedures or surgical remedies for the complaints.

Conversion disorder. This disorder was previously labeled *hysteria.* Its symptoms are a loss of or alteration in physical functioning, which may include paralysis. The physical symptoms occur in the absence of organic pathology and are instead apparently the expression of an underlying emotional conflict. The characteristic motor symptoms of conversion disorder include the paralysis of the voluntary muscles of an arm or leg, tremor, tics, and other disorders of movement or gait. The neurological symptoms may be widely distributed and may not conform with medical knowledge of nerve distribution. Blindness, deafness, loss of sensation in arms or legs, the feeling of "pins and needles," and an increased sensitivity to pain in a limb may also be present.

Symptoms usually occur in a setting of extreme psychological stress and appear suddenly. The course of the disorder is variable, with recovery often occurring in a few days but with symptoms persisting for years or decades in chronic cases that remain untreated.

The causation of conversion disorder has been linked with fixations (*i.e.,* arrested stages in the individual's early psychosexual development). Freud's theory that threatening or emotionally charged thoughts are repressed out of consciousness and converted into physical symptoms is still widely accepted. The treatment of conversion disorder thus requires psychological rather than pharmacological methods, notably the exploration of the individual's underlying emotional conflicts. Conversion disorder can also be considered as a form of "illness behaviour"; *i.e.,* the person uses the symptoms to gain a psychological advantage in social relationships, either by gathering sympathy or by being relieved of burdensome or stressful obligations and withdrawing from emotionally disturbing or threatening situations. Thus it may be advantageous to the person, in a psychological sense, to have the consequences of the symptoms.

Hypochondriasis. Hypochondriasis is a preoccupation with physical signs or symptoms that the person unrealistically interprets as abnormal, leading to the fear or belief that he is seriously ill. There may be fears about the development of physical or mental symptoms without any such existing, a belief that actual but minor symptoms are of dire consequence, or an experience of normal bodily sensations as threatening symptoms. A thorough physical examination may find no organic cause for the physical signs the individual is concerned about, but the examination fails to relieve his unrealistic fears about having a serious disease. The symptoms of hypochondriasis may occur with mental illnesses other than anxiety, such as depression or schizophrenia.

The onset of this disorder may be associated with precipitating factors such as an actual organic disease with physical and psychological aftereffects—*e.g.,* coronary thrombosis in a previously fit man. It often begins during the fourth and fifth decades of life but is also common at other times, during pregnancy, for example. Treatment aims to provide understanding and support and to reinforce healthy behaviour; antidepressant medications may be used to relieve depressive symptoms.

Psychogenic pain disorder. In psychogenic pain disorder the main feature is a persistent complaint of pain in the absence of organic disease and with evidence of a psychological cause. The pattern of pain may not conform to the known anatomic distribution of the nervous system. Psychogenic pain may occur as part of hypochondriasis or as a symptom of a depressive disorder. Appropriate treatment depends on the context of the symptom.

Dissociative disorders. A dissociative disorder is a syndrome in which one or a group of mental processes are split off, or dissociated, from the rest of the psychological apparatus so that their function is lost, altered, or impaired. Dissociative symptoms have often been regarded as the mental counterparts of the physical symptoms displayed in conversion disorders. Since the dissociation may be an unconscious mental attempt to protect the individual from threatening impulses or emotions that are repressed, the conversion into physical symptoms and the dissociation of mental processes can be seen as related defense mechanisms arising in response to emotional conflict.

In dissociative disorders there is a sudden, temporary alteration in the person's consciousness, sense of identity, or motor behaviour. There may be an apparent loss of memory of previous activities or important personal events, with amnesia for the episode itself after recovery. These are rare conditions, and it is important to exclude organic causes.

In dissociative amnesia there is a sudden loss of memory that may appear total; the individual can remember nothing about his previous life or even his name. The amnesia may be localized to a short period of time associated with a traumatic event, or it may be selective, affecting the person's recall of some, but not all, of the events during a particular time. In psychogenic fugue, the individual wanders away from home or place of work and assumes a new identity; he cannot remember his previous identity and upon recovering cannot recall the events that occurred while he was in the fugue state. In many cases the disturbance lasts only a few hours or days and involves only limited travel. Severe stress frequently triggers this disorder.

Multiple personality disorder

Dissociative identity disorder, previously called multiple personality disorder, is a rare and remarkable dissociative disorder in which two or more distinct and independent personalities develop in a single individual. Each of these personalities inhabits the person's conscious awareness to the exclusion of the others at particular times. This disorder frequently arises as a result of traumas suffered during childhood and is best treated by psychotherapy, which seeks to reunite the various personalities into a single, integrated one.

In depersonalization disorder a person feels or perceives his body or self as being unreal, strange, altered in quality, or distant. This state of self-estrangement may take the form of feeling as if one is machinelike, is living in a dream, or is not in control of one's actions. Derealization, or feelings of unreality concerning objects outside one's self, often occurs at the same time. Depersonalization disorder may occur alone in neurotic persons but is more often associated with phobic, anxiety, or depressive symptoms. It most commonly occurs in younger women and may persist for many years. Persons find the experience of depersonalization intensely difficult to describe and often fear that others will think them insane. Organic conditions, especially temporal lobe epilepsy, must be excluded before making a diagnosis of neurosis when depersonalization occurs. As with other neurotic syndromes, it is more common to see many different symptoms than to see depersonalization alone.

The causes of depersonalization are obscure, and there is no specific treatment for it. When the symptom arises in the context of another psychiatric condition, treatment is aimed at that illness.

Personality disorders. Personality is the characteristic way in which an individual thinks, feels, and behaves; it accounts for the ingrained behaviour patterns of the individual and allows the prediction of how he will act in particular circumstances. Personality embraces a person's moods, attitudes, and opinions and is most clearly expressed in interactions with other people. A personality disorder is a deeply ingrained, long-enduring, maladaptive,

and inflexible pattern of thinking, feeling, and behaving that either significantly impairs an individual's social or occupational functioning or causes subjective distress.

A personality disorder may occur with another psychiatric condition or on its own. The causes of personality disorders are obscure. There is undoubtedly a constitutional and therefore hereditary element in determining personality type. Psychological and environmental factors are also important in causation.

Some generally accepted types of personality disorder are listed below. It is important to recognize that simply exhibiting the trait or even having it to an abnormal extent is not enough to constitute disorder—for that, the degree of abnormality must cause disturbance to the individual or to society. Because personality traits are, by definition, virtually permanent, these disorders are only partially, if at all, amenable to treatment. The most effective treatment combines various types of group, behavioral, and cognitive psychotherapy. The behavioral manifestations of personality disorders often tend to diminish in their intensity in middle and old age.

Paranoid personality disorder. In this disorder there is a pervasive and unjustified suspiciousness and mistrust of others, whose words and actions are misinterpreted as having special significance for, and as being directed against, the individual. Sometimes such people are guarded, secretive, aggressive, quarrelsome, and litigious, and they are excessively sensitive to the implied criticism of others.

Schizoid personality disorder. In this disorder there is a disinclination to interact with others; the individual appears aloof, withdrawn, indifferent, unresponsive, and uninterested. Such a person prefers solitary to gregarious pursuits, involvement with things rather than with people, and often appears humourless or dull.

Schizotypal personality disorder. This category has been used to describe people who show various oddities or eccentricities of thought, speech, perception, or behaviour (*e.g.*, bizarre fantasies or persecutory delusions) but whose symptoms are not severe enough to be labeled as schizophrenic.

Obsessive-compulsive personality disorder. A person with this disorder shows prominent overscrupulous, perfectionistic traits that are expressed in feelings of insecurity, self-doubt, meticulous conscientiousness, indecisiveness, and rigidity of behaviour. The person is preoccupied with rules, procedures, and efficiency, is overly devoted to work and productivity, and is usually deficient in the ability to express warm or tender emotions. This disorder is more common in men and is in many ways the antithesis of antisocial personality disorder (see below).

Avoidant personality disorder. A person with this disorder shows extreme sensitivity to rejection and may lead a socially withdrawn life. Nevertheless, the person is not asocial and does show a great desire for companionship but needs unusually strong guarantees of uncritical acceptance. Persons with this disorder are commonly described as having an "inferiority complex."

Dependent personality disorder. This category is used to describe individuals who subordinate their own needs and responsibility over major areas of their lives to the control of others. Persons with this disorder lack self-confidence and may experience intense discomfort when alone. Women are affected with this condition more often than men.

Histrionic personality disorder. People with this disorder are overly dramatic and intensely expressive, egocentric, highly reactive, and excitable. They exhibit a tendency to call attention to themselves, crave novelty and excitement, and may be dependent and suggestible. This disorder is more common in women than men.

Antisocial personality disorder. This disorder is marked by a personal history of chronic and continuous antisocial behaviour, in which the rights of others are violated, and by poor or nonexistent job performance. It is manifested in persistent criminality, sexual promiscuity or aggressive sexual behaviour, and drug use. People with this disorder are impulsive, mendacious, irresponsible, and callous; they feel no guilt over their antisocial acts and fail to learn from their mistakes. The symptoms are usually prominent by adolescence. In order to be diagnosed with antisocial personality disorder, an individual must exhibit such symptoms before the age of 15. Antisocial personalities are less liable to criminal acts as they grow older, but there remains a high risk of suicide, accidental death, drug or alcohol abuse, and a tendency toward interpersonal problems. Antisocial personality disorder is more common in men than in women.

Narcissistic personality disorder. A person with this disorder has a grandiose sense of self-importance and a preoccupation with fantasies of success, power, and achievement.

Borderline personality disorder. Borderline personality disorder is characterized by an extraordinarily unstable mood and self-image. Individuals with this disorder may exhibit intense episodes of anger, depression, or anxiety. Self-injury is also a common symptom of this disorder.

Psychosexual disorders. The following section discusses disorders of gender identity and preferences for unusual or bizarre sexual practices or objects. Psychosexual dysfunctions such as impotence are treated in the article SEXUAL BEHAVIOUR, HUMAN.

Gender identity disorder. In gender identity disorder a person feels a discrepancy between his anatomic sex and the gender that he ascribes to himself. This disorder is much more common in males than females. The individual claims that he is a member of the opposite sex—"a female mind trapped in a male body." An individual with gender identity disorder may assume the dress and behaviour of and participate in activities commonly associated with the opposite sex and may even use hormones and surgery to achieve the physical characteristics of the opposite sex. The cause of the condition is unknown. Individuals with this disorder have a significant risk of developing depression and an increased risk of suicide. Psychiatric treatment is generally supportive in type. Persons with gender identity disorder may choose to have sex reassignment surgery, a procedure in which the body, including the genitals, is surgically altered to look like that of the opposite sex. Sex-reassignment surgery requires following carefully prescribed standards.

Paraphilias. Paraphilias, or sexual deviations, are defined as unusual fantasies, urges, or behaviours that are recurrent and sexually arousing. These urges must occur for at least six months and cause distress to the individual in order to be classified as a paraphilia. In fetishism inanimate objects (*e.g.*, shoes) are the person's sexual preference and means of sexual arousal. In transvestism the recurrent wearing of clothes of the opposite sex is performed to achieve sexual excitement. In pedophilia an adult has sexual fantasies about or engages in sexual acts with a prepubertal child of the same or opposite sex.

In exhibitionism repeated exposure of the genitals to an unsuspecting stranger is used to achieve sexual excitement. In voyeurism observing the sexual activity of others repeatedly is the preferred means of sexual arousal. In sadomasochism the individual achieves sexual excitement as either the recipient or the provider of pain, humiliation, or bondage.

There are, of course, other unusual sexual objects or acts that may be used for gratification. The causes of these conditions are generally not known. Behavioral, psychodynamic, and pharmacological methods have been used with varying efficacy to treat these disorders.

Disorders usually first evident in infancy, childhood, or adolescence. Children are usually referred to a psychiatrist or therapist because of a parent's or some other adult's complaints or concern over the child's behaviour or development. Family problems, particularly difficulties in the parent–child relationship, are often an important causative factor in the symptomatic behaviour of the child. For a child psychiatrist, the observation of behaviour is especially important, as the child may not be able to express his feelings in words. Isolated psychological symptoms are extremely common in children. Boys are affected twice as often as girls.

Attention-deficit disorders. Children with these disorders show a degree of inattention and impulsiveness that is markedly inappropriate for their stage of development.

Gross overactivity in children can have many causes, including anxiety, conduct disorder (see below), or the effects of living in institutions. Learning difficulties and antisocial behaviour may occur secondarily. This syndrome is 10 times more common in boys than in girls.

Conduct disorders. These are the most common psychiatric disorders in older children and adolescents, accounting for nearly two-thirds of disorders in those aged 10 and 11 years. Abnormal conduct more serious than ordinary childish mischief persistently occurs; lying, disobedience, aggression, truancy, delinquency, and deterioration of work may occur at home or at school. Vandalism, drug and alcohol abuse, and early sexual promiscuity may also occur. The most important causative factors are the family background; broken homes, unstable and rejecting families, institutional care in childhood, and a poor social environment are frequently present in such cases.

Anxiety disorders. Neurotic or emotional disorders in children are similar to the adult conditions except that they are often less clearly differentiated. In anxiety disorders of childhood, the child is fearful, timid with other children, and overdependent and clinging toward the parents. Physical symptoms, sleep disturbance, and nightmares occur. Separation from the parent or from the home environment is a major cause of this anxiety.

Anorexia nervosa and bulimia nervosa

Eating disorders. Anorexia nervosa usually starts in late adolescence and is about 20 times more common in girls than boys. This disorder is characterized by a failure to maintain one's body weight at the normal level for an individual's age and height; weight loss is at least 15 percent of the ideal body weight. Weight loss occurs because of an intense desire to be thin, a fear of gaining weight, or a disturbance in the way in which one sees the body weight or shape. Postmenarchal females with anorexia nervosa usually experience amenorrhea (*i.e.,* the absence of at least three consecutive menstrual periods). Though grossly thin, individuals with anorexia nervosa nevertheless believe that they are fat. They will go to enormous lengths to resist eating food and to lose weight, including food avoidance, self-induced vomiting, and vigorous exercise. Medical complications of anorexia nervosa can be life-threatening.

The condition appears to start with an individual's voluntary control of food intake in response to social pressures such as peer conformity. The disorder is exacerbated by troubled relations within the family. It is much more common in developed, wealthy societies and in girls of higher socioeconomic class. Treatment includes persuading the person to accept and cooperate with medical therapy, achieving weight gain, and helping the person maintain weight by psychological and social therapy.

Bulimia nervosa is characterized by excessive overeating binges combined with inappropriate methods of stopping weight gain such as self-induced vomiting, laxatives, or diuretics. Repetition of the cycle can lead to serious medical complications, such as dental decay or dehydration, and can be fatal. Like persons with anorexia nervosa, individuals who have bulimia nervosa show great concern for their weight and body shape; the majority, however, are close to their proper weight. Anorexia nervosa and bulimia nervosa may occur simultaneously in the same person. Depression, anxiety, and low self-esteem may be associated with the disorder.

Autistic disorder. Psychotic disorders are very rare in childhood, and of these about one-half are cases of autistic disorder. Boys are affected three times as often as girls. Autistic disorder begins in the first two years of life and is more common in the upper socioeconomic classes. The child exhibits an inability to make warm emotional relationships, has a severe speech and language disorder, and exhibits a desire for routine in which he shows distress if thwarted from his stereotyped behaviour. There is some evidence to support genetic and organic factors in the causation of autistic disorder. Treatment involves management of the abnormal behaviour, training in life skills and occupational activities, and counseling for the family.

Other childhood disorders. Stereotyped movement disorders involve the exhibition of tics in differing patterns. A tic is an involuntary, purposeless jerking movement of a group of muscles or the involuntary production of noises or words. Tics may affect the face, head, and neck or, less commonly, the limbs or trunk. Tourette's syndrome is typified by multiple tics and involuntary vocalization, which sometimes includes the uttering of obscenities.

Other physical symptoms that are often listed among psychiatric disorders of childhood include stuttering, enuresis (*i.e.,* the repeated involuntary emptying of urine from the bladder during the day or night), encopresis (*i.e.,* the repeated voiding of feces into inappropriate places), sleepwalking, and night terror. These symptoms are not necessarily evidence of emotional disturbance or of some other mental illness. Behavioral methods of treatment are usually effective.

Other mental disorders. *Factitious disorders.* Factitious disorders are characterized by physical or psychological symptoms that are voluntarily self-induced; they are distinguished from conversion disorder, in which the physical symptoms are produced unconsciously. In factitious disorders, although the person's attempts to create or exacerbate the symptoms of an illness are voluntary, such behaviour is neurotic in that the individual is unable to refrain from it; *i.e.,* his goals, whatever they may be, are involuntarily adopted. In malingering, by contrast, the person stimulates or exaggerates an illness or disability to obtain some kind of discernible personal gain or to avoid an unpleasant situation; *e.g.,* a prison inmate may simulate madness to obtain more comfortable living conditions. It is important to recognize factitious disorders as evidence of psychological disturbance.

Impulse-control disorders. Persons with these conditions demonstrate a failure to resist desires, impulses, or temptations to perform an act that is harmful to the individual or to others. The individual experiences a feeling of tension before committing the act and a feeling of release or gratification upon completing it. The behaviours involved include pathological gambling, pathological setting of fires (pyromania), pathological stealing (kleptomania), and recurrent pulling of hair (trichotillomania).

Adjustment disorders. These are conditions in which there is an inappropriate reaction to an external stress occurring within three months of the stress. The symptoms may be out of proportion to the degree of stress, or they may be maladaptive in the sense that they prevent the individual from coping adequately in his social or occupational setting. These disorders are often associated with other mood or anxiety disorders. (A.C.P.S./L.B.An.)

Treatment of mental disorders

HISTORICAL OVERVIEW

Early history. References to mental disorders in early Egyptian, Indian, Greek, and Roman writings show that the physicians and philosophers who contemplated problems of human behaviour regarded mental illnesses as a reflection of the displeasure of the gods or as evidence of demoniac possession. Only a few realized that individuals with mental illnesses should be treated humanely rather than exorcised, punished, or banished. Certain Greek medical writers, however, notably Hippocrates (flourished 400 BC), regarded mental disorders as diseases to be understood in terms of disturbed physiology. Hippocrates and his followers emphasized natural causes, clinical observation, and brain pathology in the study of mental disorders. Later Greek medical writers, including those who practiced in Imperial Rome, prescribed treatments for mental illness, including a quiet environment, work, and the use of drugs such as the purgative hellebore. It is probable that most people with psychoses during ancient times were cared for by their families and that those who were thought to be dangerous to themselves or others were detained at home by relatives or hired keepers.

During the early Middle Ages in Europe, primitive thinking about mental illness reemerged, and witchcraft and demonology were used to account for the symptoms and behaviour of people with psychoses. At least some of those who were deemed insane were looked after by the religious orders, which offered care for the sick generally. The empirical and quasi-scientific Greek tradition in medicine was maintained not by the Europeans but by the Muslim

Arabs, who are usually credited with the establishment of asylums for the mentally ill in the Middle East as early as the 8th century. In medieval Europe in general it seems that the mentally ill were allowed their freedom, provided they were not regarded as dangerous. The founding of the first hospital in Europe devoted entirely to the care of the mentally ill probably occurred in Valencia, Spain, in 1407–09, though this has also been said of a hospital established in Granada in 1366–67.

Brutal treatment of the mentally ill

From the 17th century onward in Europe, there was a growing tendency to isolate deviant people, including the mentally ill, from the rest of society. Thus, such socially unwanted people as the mentally ill were confined together with the disabled, vagrants, and delinquents. Those of the mentally ill who were regarded as violent were often chained to the walls of prisons and were treated in a barbarous and inhumane way.

In the 17th and 18th centuries, the development of European medicine and the rise of empirical methods of medicoscientific inquiry were paralleled by an improvement in public attitudes toward the mentally ill. By the end of the 18th century, concern over the care of the mentally ill had become so great among educated people in Europe and North America that governments were forced to act. After the French Revolution the physician Philippe Pinel was placed in charge of the Bicêtre, the hospital for the mentally ill in Paris. Under Pinel's supervision a completely new approach to the care of mental patients was introduced. Chains and shackles were removed from the patients, and, in place of dungeons, the mentally ill were provided with sunny rooms and were permitted to exercise on the hospital grounds. Among other reformers were the British Quaker layman William Tuke, who established the York Retreat for the humane care of the mentally ill in 1796, and the physician Vincenzo Chiarugi, who published a humanitarian regime for his hospital in Florence in 1788. In the mid-19th century Dorothea Dix led a campaign to increase public awareness of the inhumane conditions that prevailed in American mental hospitals, and her efforts led to widespread reforms both in the United States and elsewhere.

The mental hospital era. Many hospitals for the mentally ill were built in the latter half of the 18th century. Some of them, like the York Retreat in England, were run on humane and enlightened lines, while others, like the York Asylum, gave rise to great scandal because of their brutal methods and filthy living conditions. In the mid-19th century an extensive program of mental hospital building was carried out in North America, Britain, and many of the countries of continental Europe. The hospitals housed poor mental patients, and their aim was to care for these individuals humanely and to relieve their families of the burden of caring for them. The approach was that of moral treatment, including work, the avoidance of physical methods of restraint, and respect for the individual patient. A widespread belief in the curability of mental illness at this time was a principal motivating factor behind such reform.

The mental hospital era was an age of reform, and there is no doubt that patients were treated much more humanely. The era produced a large number of segregated institutions in which a much higher proportion of the mentally ill was confined than previously. But the medical reformers' early hopes of successful cures were not vindicated, and by the end of the 19th century the hospitals had become overcrowded, and custodial care had replaced moral treatment.

The biological movement. Along with humanitarian reforms in hospital practice and treatment methods during the late 18th and 19th centuries, there was a resurgence of medical and scientific interest in psychiatric theory and practice. Fundamental strides were made during this period in establishing a scientific basis for the study of mental disorders. A long series of observations by clinicians in France, Germany, and England culminated in 1883 in a comprehensive classification of mental disorders by the German psychiatrist Emil Kraepelin. His classification system served as the basis for all subsequent ones, and the cardinal distinction he made between schizophrenia and bipolar disorder still stands.

Rapid advances in various branches of medicine led in the later 19th century to the expectation of discovering specific brain lesions that were thought to cause the various forms of mental disorder. While this research did not attain the results that were expected, the scientific emphasis was productive in that it did elucidate the gross and microscopic pathology of many brain disorders that can produce psychiatric disabilities. Nevertheless, many of the psychotic disorders, notably schizophrenia and bipolar disorder, frustrated the effort to find causative agents in cellular pathology. It became apparent that other explanations had to be found for the many puzzling aspects of mental disorders in general, and these explanations emerged in a wave of psychological rather than physical explanations.

Development of psychotherapy. Foremost among these was that of psychoanalysis, which originated in the work of the Viennese neurologist Sigmund Freud. Having studied under the French neurologist Jean-Martin Charcot, Freud originally used well-known techniques of hypnosis to treat patients suffering from what was then called hysterical paralysis and other neurotic syndromes. Freud and his colleague Josef Breuer observed that their patients tended to relive earlier life experiences that could be associated with the symptomatic expression of their illnesses. When these memories and the emotions associated with them were brought to consciousness during the hypnotic state, the patients showed improvement. Observing that most of his patients proved able to talk about such memories without being under hypnosis, Freud evolved the technique of free association (*i.e.*, production by the patients, aloud and without suppression or self-censorship of any kind, of the thoughts and feelings about whatever was uppermost in their minds) as a means of access to the unconscious. From this beginning Freud gradually developed what became known as psychoanalysis. Other features of the new procedure included the study of dreams, the interpretation of "resistances" on the part of the patient, and the handling by the therapist of transference (*i.e.*, the patient's feelings toward the analyst that reflected previously experienced feelings toward parents and other important figures in his early life). Freud's work, though complex and controversial in many of its aspects, laid the basis for modern psychotherapy in its use of free association and its emphasis on unconscious and irrational mental processes as causative factors in mental illness. This emphasis on purely psychological factors as a basis for both causation and treatment was to become the cornerstone of most subsequent psychotherapies.

Freud's discoveries

Variations of the original psychoanalytic technique were introduced by several of Freud's colleagues who parted company with him. Analytic psychology, devised by Carl Jung, placed less emphasis on free association and more on the interpretation of dreams and fantasies. Special importance was given to the collective unconscious, a reservoir of shared unconscious wisdom and ancestral experience that entered consciousness only in symbolic form to influence thought and behaviour. Jungian analysts sought clues to their patients' problems in the archetypal nature of myths, stories, and dreams. Individual psychology, devised by Alfred Adler, emphasized the importance of the individual's drive toward power and of his unconscious feelings of inferiority. The therapist was concerned with the patient's compensations for his inferiority, as well as with his social relationships.

Development of physical and pharmacological treatments. During the early decades of the 20th century, the principal approaches to the treatment of mental disorders were psychoanalytically derived psychotherapies, used to treat people with neuroses, and custodial care in mental hospitals, for those with psychoses. But beginning in the 1930s these methods began to be supplemented by physical approaches using drugs, electroconvulsive therapy, and surgery. The first successful physical treatment in psychiatry was the induction of malaria in patients with a fatal form of neurosyphilis called general paresis. The malarial treatment stemmed from the observation that some psychotic patients improved during febrile illnesses. In 1933 the Polish psychiatrist Manfred Sakel reported that psychotic symptoms of patients with schizophrenia were improved by re-

peated insulin-induced comas. (Neither of these treatments is in use today.) The treatment of symptoms of schizophrenia by convulsions, originally induced by the injection of camphor, was reported in 1935 by the psychiatrist Ladislaus Joseph von Meduna in Budapest. An improvement in this approach was the induction of convulsions by the passage of an electrical current through the brain, a technique introduced by Italian psychiatrists Ugo Cerletti and Lucio Bini in 1938. Electroconvulsive treatment was more successful in alleviating states of severe depression than in treating symptoms of schizophrenia. Psychosurgery, or surgery performed to treat mental illness, was introduced by the Portuguese neurologist António Egas Moniz in the 1930s. The procedure Moniz originated, leucotomy, or lobotomy, was widely performed during the next two decades in the treatment of patients with schizophrenia, intractable depression, and severe obsessional states. The procedure was later abandoned, however, largely because its therapeutic effects could be better obtained by the use of newly developed medications.

Lobotomy

The decades after World War II were marked by the first safe and effective applications of medications in the treatment of mental disorders. Prior to the 1950s such sedative compounds as bromides and barbiturates had been used to quiet or sedate patients, but these drugs were general in their effect and did not target the specific symptoms of mood disturbances or psychotic disorders. Many of the medications that subsequently proved effective in treating such conditions were recognized serendipitously—*i.e.*, when researchers administered them to patients just to see what would happen, or when they were administered to treat one medical condition and were instead found to be helpful in alleviating the symptoms of a mental disorder.

The first effective pharmacological treatment of psychosis was the treatment of mania with lithium, introduced by the Australian psychiatrist J.F.J. Cade in 1949. Lithium, however, generated little interest until its dramatic effectiveness in the maintenance treatment of bipolar affective disorder was reported in the mid-1960s. Chlorpromazine, the first of a long series of highly successful antipsychotic drugs, was synthesized in France in 1950 during work on antihistamines. It was used in anesthesia before its antipsychotic and tranquilizing effects were reported in France in 1952. The first tricyclic antidepressant drug, imipramine, was originally designed as an antipsychotic drug and was investigated by the Swiss psychiatrist Roland Kuhn. He found it ineffective in treating symptoms of schizophrenia but observed its antidepressant effect, which he reported in 1957. A drug used in the treatment of tuberculosis, iproniazid, was found to be effective as an antidepressant in the mid-1950s. It was the first monoamine oxidase inhibitor to be used in psychiatry. The first modern anxiety-relieving drug was meprobamate, which was originally introduced as a muscle relaxant. It was soon overtaken by the pharmacologically rather similar but clinically more effective chlordiazepoxide, which was synthesized in 1957 and marketed as Librium in 1960. This drug was the first of the extensively used benzodiazepines. These and other drugs had a revolutionary impact not only on psychiatry's ability to relieve the symptoms and suffering of people with a wide range of mental disorders but also on the institutional care of the mentally ill.

Deinstitutionalization. Between about 1850 and 1950 there was a steady increase in the number of patients staying in mental hospitals. In England and Wales, for example, there were just over 7,000 such patients in 1850, nearly 120,000 in 1930, and nearly 150,000 in 1954. Then a steady decline in the number of occupied beds began, reaching just over 100,000 in 1970 and 75,000 in 1980, a decrease of almost 50 percent. The same process began in the United States in 1955 but continued at a more rapid rate. The decrease, from just under 560,000 in 1955 to just over 130,000 in 1980, was one of more than 75 percent. In both countries it became official policy to replace mental hospital treatment with community care, involving district general hospital psychiatric units in Britain and local mental health centres in the United States. This dramatic change can be partly attributed to the introduction of antipsychotic medications, which drastically changed the atmosphere of mental hospital wards. With the recovery of lucidity and calmness, many patients with psychoses could return to their homes and live at least a partially normal existence instead of spending their lives sequestered in mental hospitals. The wholesale release of mental patients into the community was not without problems, however, since many areas lacked the facilities to support and maintain such patients, many of whom thus received inadequate care.

Development of behaviour therapy. In the 1950s and '60s a new type of therapy, called behaviour therapy, was developed. In contrast to the existing psychotherapies, its techniques were based on theories of learning derived from research on classical conditioning carried out by Ivan Pavlov and others and from the work of such American behaviourists as John B. Watson and B.F. Skinner. Behavioral therapy developed when the theoretical principles that were originally developed from experiments with animals were applied to the treatment of patients.

In 1920 Watson experimentally induced a phobia of rats in a small boy, and in 1924 Mary Cover Jones reported the extinction of phobias in children by gradual desensitization. Modern behaviour therapy began with the description by the South African psychiatrist Joseph Wolpe of his technique of systematically desensitizing a patient with phobias, beginning by exposing him to the least and gradually progressing to the most feared object or situation. Behavioral therapies were more quickly adopted in Europe than in the United States, where psychoanalytic precepts had exercised a particular dominance over psychiatry, but by the 1980s behavioral therapies were also well established in the United States.

The mental health profession in the late 20th century. There has been a great increase in the number of mental health professionals since World War II. In the United States the number of psychiatrists was 3,000 in 1939 but had increased to more than 50,000 by the early 1990s. Nonmedical mental health professionals have also increased substantially in number. Clinical psychologists, who at one time largely administered psychometric tests, now also provide psychotherapy and behaviour therapy. Psychiatric social workers also have become psychotherapists and play prominent roles in mental health centres. There are new roles for nurses, including behaviour therapy and the management of chronic mental illness in the community.

Psychotherapy retains a major role in the mental health profession. Subsequent to the development of psychoanalysis, the varieties of psychotherapy have increased and multiplied to more than 250 different therapies. The repertoire of medications used in the treatment of mental illness has continued to grow as new drugs are developed or new applications of existing ones are discovered. Research on the biochemical and genetic causes of mental disease continues to make headway in explicating the causes of various disorders. The triad of psychotherapy, medications, and counseling affords an unprecedented array of approaches, techniques, and procedures for alleviating the symptoms of people with mental disorders.

PHYSIOLOGICAL TREATMENTS

Pharmacological treatments. *Antipsychotic agents.* Antipsychotic medications, which are also known as neuroleptics and major tranquilizers, belong to several different chemical groups but are similar in their therapeutic effects. These medications have a calming effect that is valuable in the relief of agitation, excitement, and violent behaviour in persons with psychoses. The drugs are quite successful in reducing the symptoms of schizophrenia, mania, and delirium, and they are used in combination with antidepressants to treat psychotic depression. The drugs suppress hallucinations and delusions, alleviate disordered or disorganized thinking, improve the patient's lucidity, and generally make an individual more receptive to psychotherapy. Patients who have previously been agitated, intractable, or grossly delusional become noticeably calmer, quieter, and more rational when maintained on these drugs. The medications have enabled many patients with episodic psychoses to have shorter stays in hospitals,

and many other patients who would have been permanently confined to institutions are able to live in the outside world because of the drugs. The antipsychotics differ in their unwanted effects: some are more likely to make the patient drowsy, some to alter blood pressure or heart rate, and some to cause tremor or slowness of movement. Some of the most widely used antipsychotic drugs are shown in Table 1.

Treatment of schizophrenia

In the treatment of schizophrenia, antipsychotic drugs partially or completely control such symptoms as delusions and hallucinations. They also protect the patient who has recovered from an acute episode of the mental illness from suffering a relapse. The newer antipsychotic medications also treat social withdrawal, apathy, blunted emotional capacity, and the other psychological deficits characteristic of the chronic stage of the illness.

No single drug seems to be outstanding in the treatment of schizophrenia. In an individual patient, one drug may be preferred to another because it produces less severe unwanted effects, and the dose of any one drug needed to produce a therapeutic effect varies widely from patient to patient. Because of these individual differences, it is common for psychiatrists to substitute a drug of a different chemical group when one drug has been shown to be ineffective despite its use in adequate dosage for several weeks.

In an acute psychotic episode a drug such as chlorpromazine, olanzepine, or haloperidol usually has a calming effect within a day or two. The control of psychotic symptoms such as hallucinations or disordered thinking may take weeks. The appropriate dosage has to be determined for each patient by cautiously increasing the dose until a therapeutic effect is achieved without unacceptable side effects.

It is not known exactly how antipsychotic medications work. One theory is that they block dopamine receptors in the brain. Dopamine is a neurotransmitter—*i.e.*, a chemical messenger produced by certain nerve cells that influence the function of other nerve cells by interacting with receptors in their cell membranes. Since schizophrenia may be caused by either the excessive release of or an increased sensitivity to dopamine in the brain, the effects of antipsychotic drugs may be due to their ability to block or inhibit dopamine transmission.

Dopamine receptor blockade is certainly responsible for the main side effects of first-generation antipsychotic medications. These symptoms, which are termed extrapyramidal symptoms (EPS), resemble those of Parkinson's disease and include tremor (shakiness) of the limbs, bradykinesia (slowness of movement with loss of facial expression, absence of arm-swinging during walking, and a general muscular rigidity), dystonia (sudden, sustained contraction of muscle groups causing abnormal postures), akathisia (a subjective feeling of restlessness leading to an inability to keep still), and tardive dyskinesia (involuntary movements, particularly involving the lips and tongue). Most extrapyramidal symptoms disappear when the drug is withdrawn. Tardive dyskinesia occurs late in the drug treatment and in about half of the cases persists even after the drug is no longer used. There is no satisfactory treatment for severe tardive dyskinesia.

Antianxiety agents. The drugs most commonly used in the treatment of anxiety are the benzodiazepines, which have replaced the barbiturates because of their vastly greater safety. One advantage of benzodiazepines is that they are less dangerous in overdose than barbiturates. A large number of benzodiazepines have been marketed, and the more common ones are listed in Table 2. Benzodiazepines differ from each other in duration of action rather than effectiveness. Smaller doses have a calming effect and alleviate both the physical and the psychological symptoms of anxiety. Larger doses induce sleep, and some benzodiazepines are marketed as hypnotics. The benzodiazepines have become among the most widely prescribed drugs in the developed world, and controversy has arisen over their excessive use by the public.

Side effects of benzodiazepines

The side effects of these medications are usually few—most often drowsiness and unsteadiness. Benzodiazepines are not lethal even in very large overdoses, but they increase the sedative effects of alcohol and other drugs. The benzodiazepines are basically intended for short- or medium-term use, since the body develops a tolerance to them that reduces their effectiveness and necessitates the use of progressively larger doses. Dependence on them may also occur, even in moderate dosages, and withdrawal symptoms have been observed in those who have used the drugs for only four to six weeks. In patients who have taken a benzodiazepine for many months or longer, withdrawal symptoms occur in between 15 and 40 percent of the cases and may take weeks or months to subside.

Withdrawal symptoms from benzodiazepines are of three kinds. Such severe symptoms as delirium or convulsions are rare. Frequently the withdrawal symptoms represent a renewal or increase of the anxiety itself. Many patients also experience other symptoms such as hypersensitivity to noise and light, as well as muscle twitching. As a result, many long-term users continue to take the drug not because of persistent anxiety but because the withdrawal symptoms are too unpleasant.

Because of the danger of dependence, benzodiazepines should be taken in the lowest possible dose for no more than a few weeks. For longer periods they should be taken intermittently, and only when the anxiety is severe.

Benzodiazepines act on specialized receptors in the brain that are adjacent to receptors for a neurotransmitter called gamma-aminobutyric acid (GABA), which inhibits anxiety. It is possible that the interaction of benzodiazepines with these receptors facilitates the inhibitory (anxiety-suppressing) action of GABA within the brain.

Other medications such as antidepressants or buspirone also are used in the treatment of anxiety.

Antidepressant agents. Many persons suffering from depression gain symptomatic relief from treatment with an antidepressant. There are several classes of antidepressant drugs, which vary in their mechanism of action and side effects. Successful treatment with such drugs relieves all the symptoms of depression, including disturbances of sleep and appetite, loss of sexual desire, and decreased energy, interest, and concentration. It usually takes two to three weeks for an antidepressant to improve a person's depressed mood significantly. Once a good response has been achieved, the drug should be continued for a further six months to reduce the risk of relapse. Antidepressants are also effective in treating other mental disorders such as panic disorder, agoraphobia, obsessive-compulsive disorder, and bulimia nervosa. Some of the most widely used antidepressant drugs are shown in Table 3.

It is widely theorized that depression is partly caused by reduced quantities or reduced activity of one or more neurotransmitters in the brain. Selective serotonin reuptake inhibitors (SSRIs), which include fluoxetine (Prozac) and sertraline (Zoloft), are thought to act by inhibiting the reabsorption of the neurotransmitter serotonin. As a result, there is an accumulation of serotonin in the brain, a

change that may be important in elevating mood. Because SSRIs interfere with only one neurotransmitter system, they have fewer, and less severe, side effects than other classes of antidepressants, which inhibit the action of several neurotransmitters. Common side effects include decreased sexual drive or ability, diarrhea, insomnia, headache, and nausea.

Tricyclic antidepressants (so called because of their three-ringed chemical structure) interfere with the reuptake of norepinephrine, serotonin, and dopamine. The side effects of these drugs are mostly due to their interference with the function of the autonomic nervous system and may include dryness of the mouth, blurred vision, constipation, and difficulty urinating. Weight gain can be a distressing side effect in persons taking a tricyclic for a long period of time. In elderly persons these drugs can cause delirium. Certain tricyclics interfere with conduction in heart muscle, and so they are best avoided in individuals with heart disease. Drug interactions occur with tricyclics, the most important being their interference with the action of certain drugs used in the treatment of high blood pressure.

Monoamine oxidase inhibitors (MAOIs) interfere with the action of monoamine oxidase, an enzyme involved in the breakdown of norepinephrine and serotonin. As a result, these neurotransmitters accumulate within nerve cells and presumably leak out onto receptors. The side effects of these drugs include daytime drowsiness, insomnia, and a fall in blood pressure when changing position. The MAOIs interact dangerously with various other drugs, including narcotics and some over-the-counter drugs used in treating colds. Persons taking an MAOI must avoid certain foods containing tyramine or other naturally occurring amines, which can cause a severe rise in blood pressure leading to headaches and even to stroke. Tyramine occurs in cheese, Chianti and other red wines, well-cured meats, and foods that contain monosodium glutamate (MSG).

Newer antidepressants, such as buproprion (Wellbutrin), have been introduced. These drugs are chemically unrelated to the other classes of antidepressants.

Use of lithium

Mood-stabilizing drugs. Lithium, usually administered as its carbonate in several small doses per day, is effective in the treatment of an episode of mania. It can drastically reduce the elation, overexcitement, grandiosity, paranoia, irritability, and flights of ideas typical of people in the manic state. It has little or no effect for several days, however, and a therapeutic dose is rather close to a toxic dose. In severe episodes antipsychotic drugs may also be used. Lithium also has an antidepressant action in some patients with melancholia.

The most important use of lithium is in the maintenance treatment of patients with bipolar disorder or with recurrent depression. When given while the patient is well, lithium may prevent further mood swings, or it may reduce either their frequency or their severity. Its mode of action is unknown. Treatment begins with a small dose that is gradually increased until a specified concentration of lithium in the blood is reached. Blood tests to determine this are carried out weekly in the early stages of treatment and later every two to three months. It may take as long as a year for lithium to become fully effective.

The toxic effects of lithium, which usually occur when there are high concentrations of it in the blood, include drowsiness, coarse tremors, vomiting, diarrhea, incoordination of movement, and, with still higher blood concentrations, convulsions, coma, and death. At therapeutic blood concentrations, lithium's side effects include fine tremors (which can be alleviated by propranolol), weight gain, passing increased amounts of urine with consequent increased thirst, and reduced thyroid function.

Carbamazepine, an anticonvulsant drug, has been shown to be effective in the treatment of mania and in the maintenance treatment of bipolar disorder. It may be combined with lithium in patients with bipolar disorder who fail to respond to either drug alone. Divalproex, another anticonvulsant, is also used in the treatment of mania.

Electroconvulsive treatment. In electroconvulsive therapy (ECT), also called shock treatment, a seizure is induced in a patient by passing a mild electric current through his brain. The mode of action of ECT is not understood. Several studies have shown that ECT is effective in treating patients with severe depression, acute mania, and some types of schizophrenia. However, the procedure remains controversial and is used only if all other methods of treatment have failed.

Prior to the administration of ECT, the patient is given an intravenous injection of an anesthetic to put him to sleep and then is administered an injection of a muscle-relaxant in order to reduce muscular contractions during the treatment. The electrical current is then applied to the brain. In bilateral ECT this is done by applying an electrode to each side of the head; in unilateral ECT both electrodes are placed over the nondominant cerebral hemisphere—*i.e.*, the right side of the head in a right-handed person. Unilateral ECT produces noticeably less confusion and memory impairment in patients, but more treatments may be needed. Patients recover consciousness rapidly after the treatment but may be confused and may experience a mild headache for an hour or two.

ECT treatments are normally given two or three times a week in the treatment of patients with depression. The number of electroconvulsive treatments required for treating depression is usually between 6 and 12. Some patients improve after the first treatment, others only after several. Once a program of ECT has been successfully completed, maintenance treatment with an antidepressant significantly decreases the patient's risk of relapse.

ECT is often considered for cases of severe depression when the patient's life is endangered because of refusal of food and fluids or because of serious risk of suicide, as well as in cases of postpartum depression, when it is desirable to reunite the mother and baby as soon as possible. ECT is often used in treating patients whose depression has not responded to adequate dosages of antidepressants.

The chief unwanted effect of ECT is impairment of memory. Some patients report memory gaps covering the period just before treatment, but others lose memories from several months before treatment. Many patients have memory difficulties for a few days or even a few weeks after completion of the treatment so that they forget appointments, phone numbers, and the like. These difficulties are transient and disappear rapidly in the vast majority of patients. Occasionally, however, patients complain of permanent memory impairment after ECT.

Psychosurgery. Psychosurgery is the destruction of groups of nerve cells or nerve fibres in the brain by surgical techniques in an attempt to relieve severe psychiatric symptoms. The removal of a brain tumour that is causing psychiatric symptoms is not an example of psychosurgery.

The classical technique of bilateral prefrontal leucotomy (lobotomy) is no longer performed because of its frequent undesirable effects on physical and mental health, in particular the development of epilepsy and the appearance of permanent undesirable changes in personality. The latter include increased apathy and passivity, lack of initiative, and a generally decreased depth and intensity of the person's emotional responses to life. In its heyday the procedure was used to treat chronically self-destructive, delusional, agitated, or violent psychotic patients. Stereotaxic surgical techniques have been developed that enable the surgeon to produce small areas of nerve cell or fibre destruction by means of metal probes inserted into accurately located parts of the brain. The nerve tissue is then destroyed by the implantation of a radioactive substance (usually yttrium) or by the application of heat or cold.

The proponents of psychosurgery claim that it is effective

in treating some patients with severe and intractable obsessive-compulsive disorder and that it may improve the behaviour of abnormally aggressive patients. Many of the therapeutic effects that were claimed for psychosurgery by its adherents are, in fact, now attainable by the use of antipsychotic and antidepressant medications. Today psychosurgery has a very small part to play in psychiatric treatment when the prolonged use of other forms of treatment has been unsuccessful and the patient is chronically and severely distressed or tormented by his symptoms. Whereas ECT is a routine treatment in certain specified conditions, psychosurgery is, at best, a last resort.

THE PSYCHOTHERAPIES

Psychotherapy implies the treatment of individuals with mental discomfort, dysfunction, or disease by psychological means by a trained therapist who adheres to a particular theory of both symptom causation and symptom relief. The American psychotherapist Jerome Frank has classified psychotherapies into religio-magical and empirico-scientific forms. The former depend on the shared beliefs of the therapist and client in magic, spirits, or other supernatural processes or powers. This article is concerned, however, with the latter forms of psychotherapy, which have been developed by modern medicine and which are performed by a member of one of the mental health professions such as a psychiatrist or a clinical psychologist.

It is usual to contrast two main forms of psychotherapy, dynamic and behavioral. They are conceptually different; behaviour therapy concentrates on alleviating a patient's overt symptoms, which are attributed to faulty learning, while dynamic therapy concentrates on understanding the meaning of symptoms and understanding the emotional conflicts within the patient that may be causing those symptoms. In their pure forms the two approaches are very different, but in practice many therapists use elements of both.

Dynamic psychotherapies. There are many variants of dynamic psychotherapy, most of which ultimately derive from the basic precepts of psychoanalysis. The fundamental approach of most dynamic psychotherapies can be traced to three basic theoretical principles or assertions: (1) Human behaviour is prompted chiefly by emotional considerations, but insight and self-understanding are necessary to modify and control such behaviour and its underlying aims; (2) A significant proportion of human emotion is not normally accessible to one's personal awareness or introspection, being rooted in the unconscious, those portions of the mind beneath the level of consciousness; (3) Any process that makes available to a person's conscious awareness the true significance of emotional conflicts and tensions that were hitherto held in the unconscious will thereby produce heightened awareness and increased stability and emotional control. The classic dynamic psychotherapies are relatively intensive talking treatments that are aimed at providing people with insight into their conscious and unconscious mental processes, with the goal of enabling them ultimately to achieve a better self-understanding.

The role of unconscious mental processes

Dynamic psychotherapy attempts to enhance the patient's personality growth as well as to alleviate symptoms. The main therapeutic forces are activated in the relationship between patient and therapist and depend both upon the empathy, understanding, integrity, and concern demonstrated by the therapist and upon the motivation, intelligence, and capacity for achieving insight manifested by the patient. The attainment of a therapeutic alliance—*i.e.*, a working relationship between patient and therapist that is based on mutual respect, trust, and confidence—provides the context in which the patient's problems can be worked through and resolved. Several of the most important forms are treated below.

Psychoanalytic psychotherapy. Classical psychoanalysis is the most intensive of all the psychotherapies in terms of time, cost, and effort. It is conducted with the patient lying on a couch and with the analyst seated out of sight but close enough to hear what the patient says. The treatment sessions last 50 minutes and are usually held four or five times a week for at least three years. The primary technique used in psychoanalysis and in other dynamic psychotherapies to enable unconscious material to enter the patient's consciousness is that of "free association." In free association, according to Freud, the patient "is to tell us not only what he can say intentionally and willingly, what will give him relief like a confession, but everything else as well that his self-observation yields him, everything that comes into his head, even if it is disagreeable for him to say it, even if it seems to him unimportant or actually nonsensical." Such a procedure is rendered difficult, first, because for a person to speak of his innermost (and often socially unacceptable) thoughts is a departure from years of practice in which he has selected what he has said to others. Free association is also difficult because the patient resists remembering repressed experiences or feelings that are connected with intense or conflicting emotions that have never been finally resolved or settled. Such repressed emotions or memories usually revolve around the patient's important personal relationships and his innermost feelings of self, and the release or recollection of such emotions in the course of treatment can be itself intensely disturbing.

Attentive listening and empathy on the part of the therapist allows the patient to express thoughts and feelings that in turn permit the uncovering of underlying emotional conflicts. In the course of treatment, the patient often seeks to project (attribute to something other than himself) the disturbing emotions he feels in the process of recollection and free association, and the person who is almost invariably selected for the focus of such projection is the psychoanalyst; that is, the patient is likely to blame his emotional distress on the analyst. In this way the patient comes to feel love or hatred, dependence or rebellion, and rivalry or rejection toward the analyst. These are the same attitudes the patient has felt but has never consciously acknowledged toward his parents or other people with whom he shared important relations earlier in life. The patient's projection onto the therapist of these feelings and behaviours that originated in earlier relationships is called transference. To facilitate the development of transference, the analyst endeavours to maintain a neutral stance toward the patient in order to serve as a "blank screen" onto which the patient can project his inner feelings. The analyst's handling of the transference situation is of vital importance in psychoanalysis—or, indeed, in any form of dynamic psychotherapy. It is through transference that the patient discovers the nature of his unconscious feelings and then becomes able to acknowledge them. Once this has been done, he often finds himself able to regard his inner feelings in a far more dispassionate and tolerant light and often feels liberated from their influence.

Transference

A major therapeutic tool in the course of treatment is interpretation. This technique helps the patient to become aware of previously repressed aspects of his emotional conflicts and to uncover the meaning of uncomfortable feelings evoked by transference. Interpretation, in turn, is used to determine the underlying psychological meaning of the patient's dreams, which are held to have a hidden or latent content that symbolizes and indirectly expresses aspects of the patient's emotional conflicts.

Individual dynamic psychotherapy. Psychoanalysis has had a profound influence, particularly on American psychiatry. During the 1980s and '90s, fewer patients entered psychoanalysis, and many analysts carry out short-term individual dynamic psychotherapy. This form of therapy usually requires 50 minutes a week for six to 18 months. The aim of treatment, as in psychoanalysis, is to increase the patient's insight (understanding of himself), to relieve his symptoms, and to improve his psychological functioning. Additionally, the therapist provides more support of and structure to the patient. Suitable patients include those with a wide range of psychological disorders and personal or social problems who wish to change and who are able to view their problems in psychological terms.

As in psychoanalysis, the patient learns to trust the therapist and becomes able to talk candidly and honestly about his most intimate thoughts and feelings. The treatment setting is less formal than in psychoanalysis, with the therapist and patient seated so that eye contact can be achieved if desired.

Treatment techniques include free association and the use of interpretation by the therapist to analyze transference, the patient's unconscious defense mechanisms, and his dreams. The therapist may ask the patient to clarify or enlarge on some point on which the therapist is not clear if this seems important in the development of the patient's symptoms. The therapist directs the patient's attention to important links, of which he seems unaware, between the present and the past, between his emotional responses to the therapist and to people important to him, and so on. The therapist may challenge the patient with the likely consequences of his resistant or maladaptive behaviour and stress instead the importance of confronting and trying to resolve his psychological difficulties.

Brief focal psychotherapy. This is a form of short-term dynamic therapy in which a time limit to the duration of the therapy is often agreed upon with the patient at the outset. Sessions lasting 30 to 60 minutes are held weekly for, typically, 5 to 15 weeks. At the beginning of treatment the therapist helps identify the patient's problem or problems, and these are made the focus of the treatment. The problem should be an important source of distress to the patient, and it should be modifiable within the time limit. The therapist is more active, directive, and confrontational than in long-term dynamic therapy and ensures that the patient keeps to the focus of treatment and is not diverted by subsidiary problems or concerns. Some therapists may aim to produce considerable emotional arousal in the patient during each session as a way to activate or highlight specific problems.

Group psychotherapy. Many types of psychological treatment may be provided for groups of patients with psychiatric disorders. This is true, for example, of relaxation training and anxiety-management training. There are also self-help groups, of which Alcoholics Anonymous is perhaps the best known. A considerable number of group experiences have been devised for people who are not suffering from any psychiatric disorder; encounter groups are a well-known example. This discussion, however, is concerned with long-term dynamic group therapy, in which 6 to 10 psychiatric patients meet with a trained group therapist, or sometimes two therapists, for 60 to 90 minutes a week for up to 18 months. Often the group is closed, *i.e.*, confined to the original group membership, even if one or more members drop out before the treatment ends. In an open group patients who have stopped attending, whether by default or because of the relief of symptoms, are replaced by new members.

The types of mental disorders considered suitable for group therapy are much the same as those suitable for individual therapy. Again the patients must want to change and must be psychologically minded. In addition, it is important that they not consider group therapy as a poor second to individual therapy.

There are many varieties of dynamic group therapy, and they differ in their theoretical background and technique. The influential model of the American psychiatrist Irvin D. Yalom provides a good example of such therapies. The therapist continually encourages the patients to direct their attention to the personal interactions occurring within the group rather than to what happened in the past to individual members or what is currently happening outside the group, although both of these areas may be considered when they are relevant. The therapist regularly draws attention to what is happening between members of the group as they learn more about themselves and test out different ways of behaving with one another. The goal in group therapy is to create a climate in which the participants can shed their inhibitions. When the members come to trust one another, they are able to provide feedback and to respond to other group members in ways that might not be possible in ordinary social interactions because of the constraints of social conventions.

Internal dynamics of group therapy

Several factors appear to be important in group therapy. The most important is group cohesion, which gives the patient a feeling of belonging, identification, and security and enables him to be frank and open and to take risks without the danger of rejection. Universality refers to the patient's realization that he is not unique, that all the other group members have problems, some of them similar to his. Optimism about what can be achieved in the group, fostered by the perception of change in others, combats demoralization. Guidance, the giving of advice and explanation, is important in the early meetings of the group and is largely a function of the therapist. What has been called vicarious learning later becomes more important; the patient observes how other group members evolve solutions to common problems and emulates desirable qualities he sees in fellow members. Catharsis, or the release of highly charged emotion, occurs within the group setting and is helpful, provided that the patient can come to understand it and appreciate its significance. Another factor that is helpful in improving self-esteem is altruism, the opportunity to give assistance to another group member.

Family therapy. Family therapists view the family as the "patient" or "client" and as more than the sum of its members. The family as a focus for treatment usually comprises the members who live under the same roof, sometimes supplemented by relatives who live elsewhere or by nonrelatives who share the family home. Therapy with couples—marital therapy—may be considered as a special type of family therapy. Family therapy may be appropriate when the person referred for treatment has symptoms clearly related to such disturbances in family function as marital discord, distorted family roles, and parent–child conflict or when the family as a unit asks for help. It is not appropriate when the patient has a severe disorder needing specific treatment in its own right.

The many theoretical approaches include psychoanalytic, systems-theory, and behavioral models. The analyst is concerned with the family's past as the cause of the present and pays attention to psychodynamic aspects of the individual members as well as of the family unit. The analyst also makes numerous interpretations and aims at increasing the insight of the members. The systems therapist, on the other hand, is interested in the present rather than the past and is often concerned not with promoting insight but rather with changing the family system, perhaps by altering the implicit and fixed rules under which it functions so that it can do so more effectively. The behaviour therapist is concerned with behaviour patterns and with pinpointing the types of reinforcement that maintain behaviour that other family members regard as undesirable. Members specify the changes in behaviour that they wish to see in one another, and strategies are devised to reinforce the desired behaviours. This approach has been shown to be effective in work with couples, when one partner promises some particular change, provided that the other reciprocates.

Treatment sessions in family therapy are rarely held more often than once a week and often take place only once every three or four weeks. Termination commonly occurs when the therapist considers that treatment has succeeded—or failed irretrievably—or the family decides to withdraw from treatment. There seems no doubt that family therapy can produce marked change within a family.

Behavioral psychotherapy. This is an approach to the treatment of mental disorders that uses a variety of methods based upon principles derived from experimental psychology, mainly that of learning theory. In the words of Joseph Wolpe, "Behavior therapy, or conditioning therapy, is the use of experimentally established principles of learning for the purpose of changing unadaptive behavior. Unadaptive habits are weakened and eliminated; adaptive habits are initiated and strengthened" (*The Practice of Behavior Therapy*, 1973).

Treatment of phobias

In the treatment of phobias, behaviour therapy seeks to modify and eliminate the avoidance response that the patient manifests when confronted with a phobic object or situation. This is crucial because, since the patient's avoidance of the anxiety-producing situation does indeed reduce his anxiety, his conditioned association of the phobic situation with the experience of anxiety remains unchallenged and frequently persists. Behaviour therapy interrupts this self-reinforcing pattern of avoidance behaviour by presenting the feared situation to the patient in a controlled manner such that it eventually ceases to produce anxiety; the strong associative link that has been built up within

him between the feared situation, the experience of anxiety, and his subsequent avoidance behaviour will thus be broken down and replaced by a less maladaptive set of responses.

The behavioral therapist is concerned with the forces and mechanisms that perpetuate the patient's present symptoms or abnormal behaviours, not with experiences in the past that may have caused them or with any postulated intrapsychic conflict. Behavioral therapy focuses on observable phenomena—*i.e.,* what is done and what is said, rather than on what must be inferred (unconscious motives and processes and symbolic meanings).

The behavioral therapist carries out a detailed analysis of the patient's behaviour problems, paying particular attention to the circumstances in which they occur, to the patient's attempts to cope with his symptoms, and to his wish for change. The goals of treatment are precisely defined and usually do not include aims such as personal growth or personality change. The relationship between patient and therapist is sometimes said to be unimportant in behaviour therapy, and it is quite true that a patient may successfully follow a behavioral therapeutic program from a book or a personal computer. Nevertheless, a patient is more likely to complete an arduous program if he trusts and respects the therapist.

Behaviour therapy has become the preferred treatment for phobic states and for some obsessive-compulsive disorders, and it is effective in many cases of sexual dysfunction and deviation. It also has an important role in the rehabilitation of patients with chronic disabling disorders.

The essence of the treatment of phobias is the controlled exposure of the patient to the objects or situations that he fears. Behaviour therapy tries to eliminate the phobia by teaching the patient how to face those situations that clearly trigger his discomfort so that he can learn to tolerate them. The exposure of the patient to the feared situation can be gradual (sometimes called desensitization) or rapid (sometimes known as flooding). Contrary to popular belief, the anxiety that is produced during exposure is not usually harmful. Even if severe panic does strike the sufferer, it will gradually evaporate and will be less likely to return in the future. Effective exposure treatments developed only as therapists learned to endure the phobic anxiety exhibited by their patients and when the therapists grew secure in the knowledge that such anxiety is much more likely to lead to the patients' improvement than to be harmful. The important point in this therapy is to persevere until the phobic anxiety starts to lessen and to be prepared to go on until it does. In general, the more rapidly and directly the worst fears are embraced by the patient, the more quickly the phobic terror fades to a tolerable mild tension.

In the technique of desensitization, the patient is first taught how to practice muscular relaxation. He then reviews the situations of which he is afraid and lists them in order of increasing fearfulness, called a "hierarchy." Finally, the patient faces the various fear-producing situations in ascending order by means of vividly imagining them, countering any anxiety by using relaxation techniques. This treatment is prolonged, and its use is restricted to feared situations that patients cannot regularly confront in real life, such as fear of lightning.

One of the most common phobic disorders treated by exposure techniques is agoraphobia (fear of open or public places). The patient is encouraged to practice exposure daily, staying in a phobic situation for at least an hour, so that anxiety has time to reach a peak and then subside. The patient must be determined to get the better of the fears and not to run away from them. People with agoraphobia cannot simply enter a dreaded crowded store, feel the familiar surge of panic, and rush out again. They must devote a full afternoon to a shopping trip. When panic strikes, the patient can sit in a corner of the store and ride out the terror. When feeling better, the patient can continue shopping. Persistence and patience are essential to conquering phobias in this way.

There is considerable evidence that exposure techniques work in most cases. Even phobias present for as long as 20 years can be overcome in a treatment program requiring no more than 3 to 15 hours of therapist time per patient. There is also considerable evidence that many people with phobias can treat themselves perfectly adequately by self-exposure without a therapist, using carefully devised self-help manuals.

Some patients with obsessive-compulsive disorders can also be helped by behaviour therapy. Several different techniques may be needed. For instance, a patient with an obsessional fear of contamination is treated by exposure, being taught to "soil" his hands with dirt and then to avoid washing them for longer and longer periods. Anxiety-management training enables the patient to withstand the anxiety he feels during the period of exposure.

This and other techniques have been shown to be effective in the treatment of compulsive rituals, with improvement occurring in more than two-thirds of patients. There is also a reduction in the frequency and intensity of obsessional thoughts that accompany the rituals. The treatment of obsessional thoughts that occur alone is much less satisfactory, however.

Other therapies. Many other types of psychotherapy were developed in the second half of the 20th century, each with its own emphasis on symptom causation and its own particular approach to treatment. Many of these therapies use classical dynamic and behavioral models in modified forms, and they may also stress the understanding and modification of cognition and the ways in which people "process" their experiences, moods, and emotions. Among these relatively recent psychotherapies are client-centred psychotherapy, developed by the American psychologist Carl R. Rogers; transactional analysis, originated by the American psychiatrist Eric Berne; the interpersonal therapies developed by the American psychiatrists Adolf Meyer and Harry Stack Sullivan; cognitive therapy, developed by the American psychiatrist Aaron T. Beck; rational-emotive psychotherapy, developed by the American psychologist Albert Ellis; and Gestalt therapy, which stems from the work of the German psychiatrist Frederick S. ("Fritz") Perls.

Another class of therapies consists of those used to care for psychotic patients, both those in hospitals and those who live in the community. Supportive psychotherapy consists of the long-term treatment of patients with chronic schizophrenia or other mental disorders. Such a therapy uses reassurance, guidance, and encouragement to help the patient cope with his disabilities and live as satisfactory a life as possible. Rehabilitation programs for chronic or episodically psychotic patients include medication maintenance; training in social skills that they may have lost while ill; occupational training to improve the patient's skills in cooking, shopping, and other domestic tasks; and industrial therapy, which usually offers the patient gainful employment under conditions of minimal stress. Family therapy is sometimes used to help relatives learn to cope with a family member who has schizophrenia and has returned home from the hospital.

Community care for individuals with schizophrenia or other psychoses who have been discharged from a hospital must provide them with medication maintenance and a minimum of psychiatric monitoring, appropriate housing facilities, some type of employment, and training in such skills as using public transport, preparing their own food, and looking after their finances. Each patient should have a case manager, a professional social worker who maintains contact and secures from governmental or social agencies the assistance that the patient needs. When provisions such as these are not made, many formerly hospitalized patients stop taking their medicine and, in effect, drop out of the mental health care system, becoming unemployed and even homeless. This phenomenon became particularly evident in the United States and to a lesser extent in western Europe when massive numbers of mental patients were released from hospitals during the 1950s and '60s after the effectiveness of antipsychotic medications had been verified. These releases were also motivated by the concerns of civil libertarians over the abuse of patients' rights in keeping them committed to mental hospitals. However, the support network of community-based mental health clinics that would have been necessary to cope

Unforeseen effects of deinstitutionalization

with the released patients was either inadequately established or nonexistent. The result was that many psychotic patients received inadequate outpatient care and supervision or encountered severe difficulties in obtaining housing or employment, becoming homeless wanderers in large urban areas. The History of Ancient Mesopotamia

Mesopotamia is a historical region in southwest Asia where the world's earliest civilization developed. The name comes from a Greek word meaning "between rivers," referring to the land between the Tigris and Euphrates rivers, but the region can be broadly defined to include the area that is now eastern Syria, southeastern Turkey, and most of Iraq. This region was the centre of a culture whose influence extended throughout the Middle East and as far as the Indus valley, Egypt, and the Mediterranean. This article covers the history of Mesopotamia from the prehistoric period up to the Arab conquest in the 7th century AD. For the history of the region in the succeeding periods, see the *Macropædia* article IRAQ. (Ed.)

Mesopotamia to the end of the Old Babylonian period

THE ORIGINS OF MESOPOTAMIAN HISTORY

The background. In the narrow sense, Mesopotamia is the area between the Euphrates and Tigris rivers, north or northwest of the bottleneck at Baghdad, in modern Iraq; it is Al-Jazīrah ("The Island") of the Arabs. South of this lies Babylonia, named after the city of Babylon. However, in the broader sense, the name Mesopotamia has come to be used for the area bounded on the northeast by the Zagros Mountains and on the southwest by the edge of the Arabian Plateau and stretching from the Persian Gulf in the southeast to the spurs of the Anti-Taurus Mountains in the northwest. Only from the latitude of Baghdad do the Euphrates and Tigris truly become twin rivers, the *rāfidān* of the Arabs, which have constantly changed their courses over the millennia. The low-lying plain of the Kārūn River in Persia has always been closely related to Mesopotamia, but it is not considered part of Mesopotamia as it forms its own river system.

Location and extent

Mesopotamia, south of Ar-Ramādī (about 70 miles, or 110 kilometres, west of Baghdad) on the Euphrates and the bend of the Tigris below Sāmarrā' (about 70 miles north-northwest of Baghdad), is flat alluvial land. Between Baghdad and the mouth of the Shaṭṭ al-'Arab (the confluence of the Tigris and Euphrates, where it empties into the Persian Gulf) there is a difference in height of only about 100 feet (30 metres). As a result of the slow flow of the water, there are heavy deposits of silt, and the riverbeds are raised. Consequently, the rivers often overflow their banks (and may even change their course) when they are not protected by high dikes. In recent times they have been regulated above Baghdad by the use of escape channels with overflow reservoirs. The extreme south is a region of extensive marshes and reed swamps, *hawrs*, which, probably since early times, have served as an area of refuge for oppressed and displaced peoples. The supply of water is not regular; as a result of the high average temperatures and a very low annual rainfall, the ground of the plain of latitude 35° N is hard and dry and unsuitable for plant cultivation for at least eight months in the year. Consequently, agriculture without risk of crop failure, which seems to have begun in the higher rainfall zones and in the hilly borders of Mesopotamia in the 10th millennium BC, began in Mesopotamia itself, the real heart of the civilization, only after artificial irrigation had been invented, bringing water to large stretches of territory through a widely branching network of canals. Since the ground is extremely fertile and, with irrigation and the necessary drainage, will produce in abundance, southern Mesopotamia became a land of plenty that could support a considerable population. The cultural superiority of north Mesopotamia, which may have lasted until about 4000 BC, was finally overtaken by the south when the people there had responded to the challenge of their situation.

The present climatic conditions are fairly similar to those of 8,000 years ago. An English survey of ruined settlements in the area 30 miles around ancient Hatra (180 miles northwest of Baghdad) has shown that the southern limits of the zone in which agriculture is possible without artificial irrigation has remained unchanged since the first settlement of Al-Jazīrah.

The availability of raw materials is a historical factor of great importance, as is the dependence on those materials that had to be imported. In Mesopotamia, agricultural products and those from stock breeding, fisheries, date palm cultivation, and reed industries—in short, grain, vegetables, meat, leather, wool, horn, fish, dates, and reed and plant-fibre products—were available in plenty and

could easily be produced in excess of home requirements to be exported. There are bitumen springs at Hīt (90 miles northwest of Baghdad) on the Euphrates (the Is of Herodotus). On the other hand, wood, stone, and metal were rare or even entirely absent. The date palm—virtually the national tree of Iraq—yields a wood suitable only for rough beams and not for finer work. Stone is mostly lacking in southern Mesopotamia, although limestone is quarried in the desert about 35 miles to the west and "Mosul marble" is found not far from the Tigris in its middle reaches. Metal can only be obtained in the mountains, and the same is true of precious and semiprecious stones. Consequently, southern Mesopotamia in particular was destined to be a land of trade from the start. Only rarely could "empires" extending over a wider area guarantee themselves imports by plundering or by subjecting neighbouring regions.

Scarcity of wood, stone, and metal

The raw material that epitomizes Mesopotamian civilization is clay: in the almost exclusively mud-brick architecture and in the number and variety of clay figurines and pottery artifacts, Mesopotamia bears the stamp of clay as does no other civilization, and nowhere in the world but in Mesopotamia and the regions over which its influence was diffused was clay used as the vehicle for writing. Such phrases as cuneiform civilization, cuneiform literature, and cuneiform law can apply only where people had had the idea of using soft clay not only for bricks and jars and for the jar stoppers on which a seal could be impressed as a mark of ownership but also as the vehicle for impressed signs to which established meanings were assigned—an intellectual achievement that amounted to nothing less than the invention of writing.

The character and achievements of ancient Mesopotamia. Questions as to what ancient Mesopotamian civilization did and did not accomplish, how it influenced its neighbours and successors, and what its legacy has transmitted are posed from the standpoint of 20th-century civilization and are in part coloured by ethical overtones, so that the answers can only be relative. Modern scholars assume the ability to assess the sum total of an "ancient Mesopotamian civilization"; but, since the publication of an article by the Assyriologist Benno Landsberger on "Die Eigenbegrifflichkeit der babylonischen Welt" (1926; "The Distinctive Conceptuality of the Babylonian World"), it has become almost a commonplace to call attention to the necessity of viewing ancient Mesopotamia and its civilization as an independent entity.

Ancient Mesopotamia had many languages and cultures; its history is broken up into many periods and eras; it had no real geographic unity, and above all no permanent capital city, so that by its very variety it stands out from other civilizations with greater uniformity, particularly that of Egypt. The script and the pantheon constitute the unifying factors, but in these also Mesopotamia shows its predilection for multiplicity and variety. Written documents were turned out in quantities, and there are often many copies of a single text. The pantheon consisted of more than 1,000 deities, even though many divine names may apply to different manifestations of a single god. During 3,000 years of Mesopotamian civilization, each century gave birth to the next. Thus classical Sumerian civilization influenced that of the Akkādians, and the Ur III empire, which itself represented a Sumero-Akkadian synthesis, exercised its influence on the first quarter of the 2nd millennium BC. With the Hittites, large areas of Anatolia were infused with the culture of Mesopotamia from 1700 BC onward. Contacts, via Mari, with Ebla in Syria, some 30 miles south of Aleppo, go back to the 24th century BC, so that links between Syrian and Palestinian scribal schools and Babylonian civilization during the Amarna period (14th century BC) may have had much older predecessors. At any rate, the similarity of certain themes in cuneiform literature and the Old Testament, such as the story of the Flood or the motif of the righteous sufferer, is due to such early contacts and not to direct borrowing.

Influence on surrounding areas

The world of mathematics and astronomy owes much to the Babylonians—for instance, the sexagesimal system for the calculation of time and angles, which is still practical because of the multiple divisibility of the number 60; the Greek day of 12 "double-hours"; and the zodiac and its signs. In many cases, however, the origins and routes of borrowings are obscure, as in the problem of the survival of ancient Mesopotamian legal theory.

The achievement of the civilization itself may be expressed in terms of its best points—moral, aesthetic, scientific, and, not least, literary. Legal theory flourished and was sophisticated early on, being expressed in several collections of legal decisions, the so-called codes, of which the best-known is the Code of Hammurabi. Throughout these codes recurs the concern of the ruler for the weak, the widow, and the orphan—even if, sometimes, the phrases were regrettably only literary clichés. The aesthetics of art are too much governed by subjective values to be assessed in absolute terms, yet certain peaks stand out above the rest, notably the art of Uruk IV, the seal engraving of the Akkad period, and the relief sculpture of Ashurbanipal. Nonetheless, there is nothing in Mesopotamia to match the sophistication of Egyptian art. Science the Mesopotamians had, of a kind, though not in the sense of Greek science. From its beginnings in Sumer before the middle of the 3rd millennium BC, Mesopotamian science was characterized by endless, meticulous enumeration and ordering into columns and series, with the ultimate ideal of including all things in the world but without the wish or ability to synthesize and reduce the material to a system. Not a single general scientific law has been found, and only rarely has the use of analogy been found. Nevertheless, it remains a highly commendable achievement that Pythagoras' law (that the sum of the squares on the two shorter sides of a right-angled triangle equals the square on the longest side), even though it was never formulated, was being applied as early as the 18th century BC. Technical accomplishments were perfected in the building of the ziggurats (temple towers resembling pyramids), with their huge bulk, and in irrigation, both in practical execution and in theoretical calculations. At the beginning of the 3rd millennium BC, an artificial stone often regarded as a forerunner of concrete was in use at Uruk (160 miles south-southeast of modern Baghdad), but the secret of its manufacture apparently was lost in subsequent years.

Writing pervaded all aspects of life and gave rise to a highly developed bureaucracy—one of the most tenacious legacies of the ancient Middle East. Remarkable organizing ability was required to administer huge estates, in which, under the 3rd dynasty of Ur, for example, it was not unusual to prepare accounts for thousands of cattle or tens of thousands of bundles of reeds. Similar figures are attested at Ebla, three centuries earlier.

Above all, the literature of Mesopotamia is one of its finest cultural achievements. Though there are many modern anthologies and chrestomathies (compilations of useful learning), with translations and paraphrases of Mesopotamian literature, as well as attempts to write its history, it cannot truly be said that "cuneiform literature" has been resurrected to the extent that it deserves. There are partly material reasons for this: many clay tablets survive only in a fragmentary condition, and duplicates that would restore the texts have not yet been discovered, so that there are still large gaps. A further reason is the inadequate knowledge of the languages: insufficient acquaintance with the vocabulary and, in Sumerian, major difficulties with the grammar. Consequently, another generation of Assyriologists will pass before the great myths, epics, lamentations, hymns, "law codes," wisdom literature, and pedagogical treatises can be presented to the reader in such a way that he can fully appreciate the high level of literary creativity of those times.

Mesopotamian literature

The classical and medieval views of Mesopotamia: its rediscovery in modern times. Before the first excavations in Mesopotamia, about 1840, nearly 2,000 years had passed during which knowledge of the ancient Middle East was derived from three sources only: the Bible, Greek and Roman authors, and the excerpts from the writings of Berosus, a Babylonian who wrote in Greek. In 1800 very little more was known than in AD 800, although these sources had served to stir the imagination of poets and artists, down to *Sardanapalus* (1821) by the 19th-century English poet Lord Byron.

Apart from the building of the Tower of Babel, the Old Testament mentions Mesopotamia only in those historical contexts in which the kings of Assyria and Babylonia affected the course of events in Israel and Judah: in particular Tiglath-pileser III, Shalmaneser V, and Sennacherib, with their policy of deportation, and the Babylonian Exile introduced by Nebuchadrezzar II. Of the Greeks, Herodotus of Halicarnassus (5th century BC, a contemporary of Xerxes I and Artaxerxes I) was the first to report on "Babylon and the rest of Assyria"; at that date the Assyrian empire had been overthrown for more than 100 years. The Athenian Xenophon took part in an expedition (during 401–399 BC) of Greek mercenaries who crossed Anatolia, made their way down the Euphrates as far as the vicinity of Baghdad, and returned up the Tigris after the famous Battle of Cunaxa. In his *Cyropaedia* Xenophon describes the final struggle between Cyrus II and the Neo-Babylonian empire. Later, the Greeks adopted all kinds of fabulous tales about King Ninus, Queen Semiramis, and King Sardanapalus. These stories are described mainly in the historical work of Diodorus Siculus (1st century BC), who based them on the reports of a Greek physician, Ctesias (405–359 BC). Herodotus saw Babylon with his own eyes, and Xenophon gave an account of travels and battles. All later historians, however, wrote at second or third hand, with one exception, Berosus (b. *c.* 340 BC), who emigrated at an advanced age to the Aegean island of Cos, where he is said to have composed the three books of the *Babylōniaka*. Unfortunately, only extracts from them survive, prepared by one Alexander Polyhistor (1st century BC), who, in his turn, served as a source for the Church Father Eusebius (d. AD 342). Berosus derided the "Greek historians" who had so distorted the history of his country. He knew, for example, that it was not Semiramis who founded the city of Babylon, but he was himself the prisoner of his own environment and cannot have known more about the history of his land than was known in Babylonia itself in the 4th century BC.

Greek accounts of Mesopotamia

Berosus' first book dealt with the beginnings of the world and with a myth of a composite being, Oannes, half fish, half man, who came ashore in Babylonia at a time when men still lived like the wild beasts. Oannes taught them the essentials of civilization: writing, the arts, law, agriculture, surveying, and architecture. The name Oannes must have been derived from the cuneiform U'anna (Sumerian) or Umanna (Akkadian), a second name of the mythical figure Adapa, the bringer of civilization. The second book of Berosus contained the Babylonian king list from the beginning to King Nabonassar (Nabu-naṣir, 747–734 BC), a contemporary of Tiglath-pileser III. Berosus' tradition, beginning with a list of primeval kings before the Flood, is a reliable one; it agrees with the tradition of the Sumerian king list, and even individual names can be traced back exactly to their Sumerian originals. Even the immensely long reigns of the primeval kings, which lasted as long as "18 sars" (= 18 × 3,600 = 64,800) of years, are found in Berosus. Furthermore, he was acquainted with the story of the Flood, with Cronus as its instigator and Xisuthros (or Ziusudra) as its hero, and with the building of an ark. The third book is presumed to have dealt with the history of Babylonia from Nabonassar to the time of Berosus himself.

Diodorus made the mistake of locating Nineveh on the Euphrates, and Xenophon gave an account of two cities, Larissa (probably modern Nimrūd [ancient Kalakh], 20 miles southeast of modern Mosul) and Mespila (ancient Nineveh, just north of Mosul). The name Mespila probably was nothing more than the word of the local Aramaeans for ruins; there can be no clearer instance of the rift that had opened between the ancient Middle East and the classical West. In sharp contrast, the East had a tradition that the ruins opposite Mosul (in north Iraq) concealed ancient Nineveh. When a Spanish rabbi from Navarre, Benjamin of Tudela, was traveling in the Middle East between 1160 and 1173, Jews and Muslims alike knew the position of the grave of the prophet Jonah. The credit for the rediscovery of the ruins of Babylon goes to an Italian, Pietro della Valle, who correctly identified the vast ruins north of modern Al-Ḥillah, Iraq (60 miles south of Baghdad); he must have seen there the large rectangular tower that represented the ancient ziggurat. Previously, other travelers had sought the Tower of Babel in two other monumental ruins: Birs Nimrūd, the massive brick structure of the ziggurat of ancient Borsippa (modern Birs, near Al-Ḥillah), vitrified by lightning, and the ziggurat of the Kassite capital, Dur Kurigalzu, at Burj 'Aqarqūf, 22 miles west of Baghdad. Pietro della Valle brought back to Europe the first specimens of cuneiform writing, stamped brick, of which highly impressionistic reproductions were made. Thereafter, European travelers visited Mesopotamia with increasing frequency, among them Carsten Niebuhr (an 18th-century German traveler), Claudius James Rich (a 19th-century Orientalist and traveler), and Ker Porter (a 19th-century traveler).

The work of Pietro della Valle

In modern times a third Middle Eastern ruin drew visitors from Europe—Persepolis, in the land of Persia east of Susiana, near modern Shīrāz, Iran. In 1602, reports had filtered back to Europe of inscriptions that were not in Hebrew, Arabic, Aramaic, Georgian, or Greek. In 1700 an Englishman, Thomas Hyde, coined the term "cuneiform" for these inscriptions, and by the middle of the 18th century it was known that the Persepolis inscriptions were related to those of Babylon. Niebuhr distinguished three separate alphabets (Babylonian, Elamite, and Old Persian cuneiform). The first promising attempt at decipherment was made by the German philologist Georg Friedrich Grotefend in 1802, by use of the kings' names in the Old Persian versions of the trilingual inscriptions, although his later efforts led him up a blind alley. Thereafter, the efforts to decipher cuneiform gradually developed in the second half of the 19th century into a discipline of ancient Oriental philology, which was based on results established through the pioneering work of Emile Burnouf, Edward Hincks, Sir Henry Rawlinson, and many others.

Today this subject is still known as Assyriology, because at the end of the 19th century the great majority of cuneiform texts came from the Assyrian city of Nineveh, in particular from the library of King Ashurbanipal in the mound of Kuyunjik at Nineveh.

Modern archaeological excavations. More than 150 years separate the first excavations in Mesopotamia—adventurous expeditions involving great personal risks, far from the protection of helpful authorities—from those of the present day with their specialist staffs, modern technical equipment, and objectives wider than the mere search for valuable antiquities. The progress of six generations of excavators has led to a situation in which less is recovered more accurately; in other words, the finds are observed, measured, and photographed as precisely as possible. At first digging was unsystematic, with the consequence that, although huge quantities of clay tablets and large and small antiquities were brought to light, the locations of the finds were rarely described with any accuracy. Not until the beginning of the 20th century did excavators learn to isolate the individual bricks in the walls that had previously been erroneously thought to be nothing more than packed clay; the result was that various characteristic brick types could be distinguished and successive architectural levels established. Increased care in excavation does, of course, carry with it the risk that the pace of discovery will slow down. Moreover, the eyes of the local inhabitants are now sharpened and their appetite for finds is whetted, so that clandestine diggers have established themselves as the unwelcome colleagues of the archaeologists.

A result of the technique of building with mud brick (mass production of baked bricks was impossible because of the shortage of fuel) was that the buildings were highly vulnerable to the weather and needed constant renewal; layers of settlement rapidly built up, creating a tell (Arabic: *tall*), a mound of occupation debris that is the characteristic ruin form of Mesopotamia. The word itself appears among the most original vocabulary of the Semitic languages and is attested as early as the end of the 3rd millennium BC. Excavation is made more difficult by this mound formation, since both horizontal and vertical axes have to be taken into account. Moreover, the depth of each level is not necessarily constant, and foundation trenches may be dug down into earlier levels. A further

The tell

problem is that finds may have been removed from their original context in antiquity. Short-lived settlements that did not develop into mounds mostly escape observation, but aerial photography can now pick out ground discolorations that betray the existence of settlements. Districts with a high water level today, such as the reed marshes (*hawrs*), or ruins that are covered by modern settlements, such as Irbil (ancient Arbela), some 200 miles north of Baghdad, or sites that are surmounted by shrines and tombs of holy men are closed to archaeological research.

Excavations in Mesopotamia have mostly been national undertakings (France, England, the United States, Germany, Iraq, Denmark, Belgium, Italy, Japan, and the former Soviet Union), but joint expeditions like the one sent to Ur (190 miles south-southeast of Baghdad) in the 1920s have become more frequent since the 1970s. The history of archaeological research in Mesopotamia falls into four categories, represented by phases of differing lengths: the first, and by far the longest, begins with the French expedition to Nineveh (1842) and Khorsabad (the ancient Dur Sharrukin, 20 miles northeast of modern Mosul; 1843–55) and that of the English to Nineveh (1846–55) and Nimrūd (ancient Kalakh, biblical Calah; 1845, with interruptions until 1880). This marked the beginning of the "classic" excavations in the important ancient capitals, where spectacular finds might be anticipated. The principal gains were the Assyrian bull colossi and wall reliefs and the library of Ashurbanipal from Nineveh, although the ground plans of temples and palaces were quite as valuable. While these undertakings had restored the remains of the Neo-Assyrian empire of the 1st millennium BC, from 1877 onward new French initiatives in Telloh (Arabic: Tall Lōḥ), 155 miles southeast of Baghdad, reached almost 2,000 years further back into the past. There they rediscovered a people whose language had already been encountered in bilingual texts from Nineveh—the Sumerians. Telloh (ancient Girsu) yielded not only inscribed material that, quite apart from its historical interest, was critical for the establishment of the chronology of the second half of the 3rd millennium BC but also many artistic masterpieces. Thereafter excavations in important cities spread to form a network including Susa, 150 miles west of Eṣfahān in Iran (France; 1884 onward); Nippur, 90 miles southeast of Baghdad (the United States; 1889 onward); Babylon, 55 miles south of Baghdad (Germany; 1899–1917 and again from 1957 onward); Ashur, modern Ash-Sharqāṭ, 55 miles south of Mosul (Germany; 1903–14); Uruk (Germany; 1912–13 and from 1928 onward); and Ur (England and the United States; 1918–34). Mention also should be made of the German excavations at Boğazköy in central Turkey, the ancient Hattusa, capital of the Hittite empire, which have been carried on, with interruptions, since 1906.

Investigations after 1925

The second phase began in 1925 with the commencement of American excavations at Yorgan Tepe (ancient Nuzi), 140 miles north of Baghdad, a provincial centre with Old Akkadian, Old Assyrian, and Middle Assyrian/Hurrian levels. There followed, among others, French excavations at Arslan Tash (ancient Hadatu; 1928), at Tall al-Aḥmar (ancient Til Barsib; 1929–31), and above all at Tall Ḥarīrī (ancient Mari; 1933 onward) and American excavations in the Diyālā region (east of Baghdad), at Tall al-Asmar (ancient Eshnunna), at Khafājī, and at other sites. Thus, excavation in Mesopotamia had moved away from the capital cities to include the "provinces." Simultaneously, it expanded beyond the limits of Mesopotamia and Susiana and revealed outliers of "cuneiform civilization" on the Syrian coast at Ras Shamra (ancient Ugarit; France, 1929 onward) and on the Orontes of northern Syria at Al-'Aṭshānah (ancient Alalakh; England, 1937–39 and 1947–49), while, since 1954, Danish excavations on the islands of Bahrain and Faylakah, off the Tigris-Euphrates delta, have disclosed staging posts between Mesopotamia and the Indus Valley Civilization. Short-lived salvage operations have been undertaken at the site of the Assad Dam on the middle Euphrates (*e.g.*, German excavations at Ḥabūba al-Kabīra, 1971–76). Italian excavations at Tall Mardīkh (ancient Ebla; 1967 onward) have yielded spectacular results, including several thousand cuneiform tablets dating from the 24th century BC.

In its third phase, archaeological research in Mesopotamia and its neighbouring lands has probed back into prehistory and protohistory. The objective of these investigations, initiated by American archaeologists, was to trace as closely as possible the successive chronological stages in the progress of man from hunter-gatherer to settled farmer and, finally, to city dweller. These excavations are strongly influenced by the methods of the prehistorian, and the principal objective is no longer the search for texts and monuments. Apart from the American investigations, Iraq itself has taken part in this phase of the history of investigation, as has Japan since 1956 and the former Soviet Union from 1969 until the early 1990s.

Finally, the fourth category, which runs parallel with the first three phases, is represented by "surveys," which do not concentrate on individual sites but attempt to define the relations between single settlements, their positioning along canals or rivers, or the distribution of central settlements and their satellites. Since shortages of time, money, and an adequate task force preclude the thorough investigation of large numbers of individual sites, the method employed is that of observing and collecting finds from the surface. Of these finds, the latest in date will give a rough termination date for the duration of the settlement, but, since objects from earlier, if not the earliest, levels work their way to the surface with a predictable degree of certainty or are exposed in rain gullies, an intensive search of the surface of the mound allows conclusions as to the total period of occupation with some degree of probability. If the individual periods of settlement are marked on superimposed maps, a very clear picture is obtained of the fluctuations in settlement patterns, of the changing proportions between large and small settlements, and of the equally changeable systems of riverbeds and irrigation canals—for, when points on the map lie in line, it is a legitimate assumption that they were once connected by watercourses.

During the four phases outlined, the objectives and methods of excavation have broadened and shifted. At first the chief aim was the recovery of valuable finds suitable for museums, but at the same time there was, from early on, considerable interest in the architecture of Mesopotamia, which has won for it the place it deserves in architectural history. Alongside philology, art history has also made great strides, building up a chronological framework by the combination of evidence from stratigraphic and stylistic criteria, particularly in pottery and cylinder seals. The discovery of graves and a variety of burial customs has thrown new light on the history of religion, stimulated by the interest of Old Testament studies. While pottery was previously collected for purely aesthetic motives or from the point of view of art history, attention has come to be paid increasingly to everyday wares, and greater insight into social and economic history is based on knowledge of the distribution and frequency of shapes and materials. The observation and investigation of animal bones and plant remains (pollen and seed analysis) have supplied invaluable information on the process of domestication, the conditions of animal husbandry, and the advances in agriculture. Such studies demand the cooperation of both zoologists and paleobotanists. In addition, microscopic analysis of the floors of excavated buildings may help to identify the functions of individual rooms.

Advances in Assyriological studies

The emergence of Mesopotamian civilization. *The Late Neolithic Period and the Chalcolithic Period.* Between about 10,000 BC and the genesis of large permanent settlements, the following stages of development are distinguishable, some of which run parallel: (1) the change to sedentary life, or the transition from continual or seasonal change of abode, characteristic of hunter-gatherers and the earliest cattle breeders, to life in one place over a period of several years or even permanently, (2) the transition from experimental plant cultivation to the deliberate and calculated farming of grains and leguminous plants, (3) the erection of houses and the associated "settlement" of the gods in temples, (4) the burial of the dead in cemeteries, (5) the invention of clay vessels, made at first by hand, then turned on the wheel and fired to ever greater degrees of hardness, at the same time receiving almost invariably

decoration of incised designs or painted patterns, (6) the development of specialized crafts and the distribution of labour, and (7) metal production (the first use of metal—copper—marks the transition from the Late Neolithic to the Chalcolithic Period).

These stages of development can only rarely be dated on the basis of a sequence of levels at one site alone. Instead, an important role is played by the comparison of different sites, starting with the assumption that what is simpler and technically less accomplished is older. In addition to this type of dating, which can be only relative, the radiocarbon, or carbon-14, method has proved to be an increasingly valuable tool since the 1950s. By this method the known rate of decay of the radioactive carbon isotope (carbon-14) in wood, horn, plant fibre, and bone allows the time that has elapsed since the "death" of the material under examination to be calculated. Although a plus/minus discrepancy of up to 200 years has to be allowed for, this is not such a great disadvantage in the case of material 6,000 to 10,000 years old. Even when skepticism is necessary because of the use of an inadequate sample, carbon-14 dates are still very welcome as confirmation of dates arrived at by other means. Moreover, radiocarbon ages can be converted to more precise dates through comparisons with data obtained by dendrochronology, a method of absolute age determination based on the analysis of the annual rings of trees.

The beginnings of agriculture

The first agriculture, the domestication of animals, and the transition to sedentary life took place in regions in which animals that were easily domesticated, such as sheep, goats, cattle, and pigs, and the wild prototypes of grains and leguminous plants, such as wheat, barley, bitter vetch, pea, and lentil, were present. Such centres of dispersion may have been the valleys and grassy border regions of the mountains of Iran, Iraq, Anatolia, Syria, and Palestine, but they also could have been, say, the northern slopes of the Hindu Kush. As settled life, which caused a drop in infant mortality, led to the increase of the population, settlement spread out from these centres into the plains—although it must be remembered that this process, described as the Neolithic Revolution, in fact took thousands of years.

Representative of the first settlements on the borders of Mesopotamia are the adjacent sites of Zawi Chemi Shanidar and Shanidar itself, which lie northwest of Rawāndūz. They date from the transition from the 10th to the 9th millennium BC and are classified as prepottery. The finds included querns (primitive mills) for grinding grain (whether wild or cultivated is not known), the remains of huts about 13 feet in diameter, and a cemetery with grave goods. The presence of copper beads is evidence of acquaintance with metal, though not necessarily with the technique of working it into tools, and the presence of obsidian (volcanic glass) is indicative of the acquisition of nonindigenous raw materials by means of trade. The bones found testify that sheep were already domesticated at Zawi Chemi Shanidar.

At Karīm Shahir, a site that cannot be accurately tied chronologically to Shanidar, clear proof was obtained both of the knowledge of grain cultivation, in the form of sickle blades showing sheen from use, and of the baking of clay, in the form of lightly fired clay figurines. Still in the hilly borders of Mesopotamia, a sequence of about 3,000 years can be followed at the site of Qal'at Jarmo, east of Kirkūk, some 150 miles north of Baghdad. The beginning of this settlement can be dated to about 6750 BC; excavations uncovered 12 archaeological levels of a regular village, consisting of about 20 to 25 houses built of packed clay, sometimes with stone foundations, and divided into several rooms. The finds included types of wheat (emmer and einkorn) and two-row barley, the bones of domesticated goats, sheep, and pigs, and obsidian tools, stone vessels, and, in the upper third of the levels, clay vessels with rough painted decorations, providing the first certain evidence for the manufacture of pottery. Jarmo must be roughly contemporary with the sites of Jericho (13 miles east of Jerusalem) and of Çatalhüyük in Anatolia (central Turkey). Those sites, with their walled settlements, seem to have achieved a much higher level of civilization, but too much weight must not be placed on the comparison because no other sites in and around Mesopotamia confirm the picture deduced from Jarmo alone. Views on the earliest Neolithic in Iraq have undergone radical revisions in the light of discoveries made since the 1970s at Qermez Dere, Nemrik, and Maghzaliyah.

About 1,000 years later are two villages that are the earliest so far discovered in the plain of Mesopotamia: Ḥassūna, near Mosul, and Tall Ṣawwān, near Sāmarrā'. At Ḥassūna the pottery is more advanced, with incised and painted designs, but the decoration is still unsophisticated. One of the buildings found may be a shrine, judging from its unusual ground plan. Apart from emmer there occurs, as the result of mutation, six-row barley, which was later to become the chief grain crop of southern Mesopotamia. In the case of Tall Ṣawwān, it is significant that the settlement lay south of the boundary of rainfall agriculture; thus it must have been dependent on some form of artificial irrigation, even if this was no more than the drawing of water from the Tigris. This, therefore, gives a date after which the settlement of parts of southern Mesopotamia would have been feasible.

Six-row barley

The emergence of cultures. For the next millennium, the 5th, it is customary to speak in terms of various "cultures" or "horizons," distinguished in general by the pottery, which may be classed by its colour, shape, hardness, and, above all, by its decoration. The name of each horizon is derived either from the type site or from the place where the pottery was first found: Sāmarrā' on the Tigris, Tall Ḥalaf in the central Jazīrah, Ḥassūna Level V, Al-'Ubaid near Ur, and Ḥājj Muḥammad on the Euphrates, not far from As-Samāwah (some 150 miles south-southeast of Baghdad). Along with the improvement of tools, the first evidence for water transport (a model boat from the prehistoric cemetery at Eridu, in the extreme south of Mesopotamia, *c.* 4000 BC), and the development of terra-cottas, the most impressive sign of progress is the constantly accelerating advance in architecture. This can best be followed in the city of Eridu, which in historical times was the centre of the cult of the Sumerian god Enki.

Originally a small, single-roomed shrine, the temple in the Ubaid period consisted of a rectangular building, measuring 80 by 40 feet, that stood on an artificial terrace. It had an "offering table" and an "altar" against the short walls, aisles down each side, and a facade decorated with niches. This temple, standing on a terrace probably originally designed to protect the building from flooding, is usually considered the prototype of the characteristic religious structure of later Babylonia, the ziggurat. The temple at Eridu is in the very same place as that on which the Enki ziggurat stood in the time of the 3rd dynasty of Ur (*c.* 2112–*c.* 2004 BC), so the cult tradition must have existed on the same spot for at least 1,500 to 2,000 years before Ur III itself. Remarkable as this is, however, it is not justifiable to assume a continuous ethnic tradition. The flowering of architecture reached its peak with the great temples (or assembly halls?) of Uruk, built around the turn of the 4th to 3rd millennium BC (Uruk Levels VI to IV).

In extracting information as to the expression of mind and spirit during the six millennia preceding the invention of writing, it is necessary to take account of four major sources: decoration on pottery, the care of the dead, sculpture, and the designs on seals. There is, of course, no justification in assuming any association with ethnic groups.

The most varied of these means of expression is undoubtedly the decoration of pottery. It is hardly coincidental that, in regions in which writing had developed, high-quality painted pottery was no longer made. The motifs in decoration are either abstract and geometric or figured, although there is also a strong tendency to geometric stylization. An important question is the extent to which the presence of symbols, such as the bucranium (a sculptured ornament representing an ox skull), can be considered as expressions of specific religious ideas, such as a bull cult, and, indeed, how much the decoration was intended to convey meaning at all.

It is not known how ancient is the custom of burying the dead in graves nor whether its intention was to main-

Burial customs

tain communication (by the cult of the dead) or to guard against the demonic power of the unburied dead left free to wander. A cemetery, or collection of burials associated with grave goods, is first attested at Zawi Chemi Shanidar. The presence of pots in the grave indicates that the bodily needs of the dead person were provided for, and the discovery of the skeleton of a dog and of a model boat in the cemetery at Eridu suggests that it was believed that the activities of life could be pursued in the afterlife.

The earliest sculpture takes the form of very crudely worked terra-cotta representations of women; the Ubaid Horizon, however, has figurines of both women and men, with very slender bodies, protruding features, arms akimbo, and the genitals accurately indicated, and also of women suckling children. It is uncertain whether it is correct to describe these statuettes as idols, whether the figures were cult objects, such as votive offerings, or whether they had a magical significance, such as fertility charms, or, indeed, what purpose they did fulfill.

Seals are first attested in the form of stamp seals at Tepe Gawra, north of Mosul. Geometric designs are found earlier than scenes with figures, such as men, animals, conflict between animals, copulation, or dance. Here again it is uncertain whether the scenes are intended to convey a deeper meaning. Nevertheless, unlike pottery, a seal has a direct relationship to a particular individual or group, for the seal identifies what it is used to seal (a vessel, sack, or other container) as the property or responsibility of a specific person. To that extent, seals represent the earliest pictorial representations of persons. The area of distribution of the stamp seal was northern Mesopotamia, Anatolia, and Iran. Southern Mesopotamia, on the other hand, was the home of the cylinder seal, which was either an independent invention or was derived from stamp seals engraved on two faces. The cylinder seal, with its greater surface area and more practical application, remained in use into the 1st millennium BC. Because of the continuous changes in the style of the seal designs, cylinder seals are among the most valuable of chronological indicators for archaeologists.

In general, the prehistory of Mesopotamia can only be described by listing and comparing human achievements, not by recounting the interaction of individuals or peoples. There is no basis for reconstructing the movements and migrations of peoples unless one is prepared to equate the spread of particular archaeological types with the extent of a particular population, the change of types with a change of population, or the appearance of new types with an immigration.

The only certain evidence for the movement of peoples beyond their own territorial limits is provided at first by material finds that are not indigenous. The discovery of obsidian and lapis lazuli at sites in Mesopotamia or in its neighbouring lands is evidence for the existence of trade, whether consisting of direct caravan trade or of a succession of intermediate stages.

Just as no ethnic identity is recognizable, so nothing is known of the social organization of prehistoric settlements. It is not possible to deduce anything of the "government" in a village nor of any supraregional connections that may have existed under the domination of one centre. Constructions that could only have been accomplished by the organization of workers in large numbers are first found in Uruk Levels VI to IV: the dimensions of these buildings suggest that they were intended for gatherings of hundreds of people. As for artificial irrigation, which was indispensable for agriculture in south Mesopotamia, the earliest form was probably not the irrigation canal. It is assumed that at first floodwater was dammed up to collect in basins, near which the fields were located. Canals, which led the water farther from the river, would have become necessary when the land in the vicinity of the river could no longer supply the needs of the population.

Beginnings of artificial irrigation

Mesopotamian protohistory. Attempts have been made by philologists to reach conclusions about the origin of the flowering of civilization in southern Mesopotamia by the analysis of Sumerian words. It has been thought possible to isolate an earlier, non-Sumerian substratum from the Sumerian vocabulary by assigning certain words on the basis of their endings to either a Neolithic or a Chalcolithic language stratum. These attempts are based on the phonetic character of Sumerian at the beginning of the 2nd millennium BC, which is at least 1,000 years later than the invention of writing. Quite apart, therefore, from the fact that the structure of Sumerian words themselves is far from adequately investigated, the enormous gap in time casts grave doubt on the criteria used to distinguish between Sumerian and "pre-Sumerian" vocabulary.

The earliest peoples of Mesopotamia who can be identified from inscribed monuments and written tradition—people in the sense of speakers of a common language—are, apart from the Sumerians, Semitic peoples (Akkadians or pre-Akkadians) and Subarians (identical with, or near relatives of, the Hurrians, who appear in northern Mesopotamia around the end of the 3rd millennium BC). Their presence is known, but no definite statements about their past or possible routes of immigration are possible.

At the turn of the 4th to 3rd millennium BC, the long span of prehistory is over, and the threshold of the historical era is gained, captured by the existence of writing. Names, speech, and actions are fixed in a system that is composed of signs representing complete words or syllables. The signs may consist of realistic pictures, abbreviated representations, and perhaps symbols selected at random. Since clay is not well suited to the drawing of curved lines, a tendency to use straight lines rapidly gained ground. When the writer pressed the reed in harder at the beginning of a stroke, it made a triangular "head," and thus "wedges" were impressed into the clay. It is the Sumerians who are usually given the credit for the invention of this, the first system of writing in the Middle East. As far as they can be assigned to any language, the inscribed documents from before the dynasty of Akkad (*c.* 2334–*c.* 2154 BC) are almost exclusively in Sumerian. Moreover, the extension of the writing system to include the creation of syllabograms by the use of the sound of a logogram (sign representing a word), such as *gi*, "a reed stem," used to render the verb *gi*, "to return," can only be explained in terms of the Sumerian language. It is most probable, however, that Mesopotamia in the 4th millennium BC, just as in later times, was composed of many races. This makes it likely that, apart from the Sumerians, the interests and even initiatives of other language groups may have played their part in the formation of the writing system. Many scholars believe that certain clay objects or tokens that are found in prehistoric strata may have been used for some kind of primitive accounting. These tokens, some of which are incised and which have various forms, may thus be three-dimensional predecessors of writing.

Precursors of writing

Sumerian is an agglutinative language: prefixes and suffixes, which express various grammatical functions and relationships, are attached to a noun or verb root in a "chain." Attempts to identify Sumerian more closely by comparative methods have as yet been unsuccessful and will very probably remain so, as languages of a comparable type are known only from AD 500 (Georgian) or 1000 (Basque)—that is, 3,000 years later. Over so long a time, the rate of change in a language, particularly one that is not fixed in a written norm, is so great that one can no longer determine whether apparent similarity between words goes back to an original relationship or is merely fortuitous. Consequently, it is impossible to obtain any more accurate information as to the language group to which Sumerian may once have belonged.

The most important development in the course of the 4th millennium BC was the birth of the city. There were precursors, such as the unwalled prepottery settlement at Jericho of about 7000 BC, but the beginning of cities with a more permanent character came only later. There is no generally accepted definition of a city. In this context, it means a settlement that serves as a centre for smaller settlements, one that possesses one or more shrines of one or more major deities, has extensive granaries, and, finally, displays an advanced stage of specialization in the crafts.

The earliest cities of southern Mesopotamia, as far as their names are known, are Eridu, Uruk, Bad-tibira, Nippur, and Kish (35 miles south-southeast of Baghdad). The surveys of the American archaeologist Robert McCormick

Adams and the German archaeologist Hans Nissen have shown how the relative size and number of the settlements gradually shifted: the number of small or very small settlements was reduced overall, whereas the number of larger places grew. The clearest sign of urbanization can be seen at Uruk, with the almost explosive increase in the size of the buildings. Uruk Levels VI to IV had rectangular buildings covering areas as large as 275 by 175 feet. These buildings are described as temples, since the ground plans are comparable to those of later buildings whose sacred character is beyond doubt, but other functions, such as assembly halls for noncultic purposes, cannot be excluded.

The major accomplishments of the period Uruk VI to IV, apart from the first inscribed tablets (Level IV B), are masterpieces of sculpture and of seal engraving and also of the form of wall decoration known as cone mosaics. Together with the everyday pottery of gray or red burnished ware, there is a very coarse type known as the beveled-rim bowl. These are vessels of standard size whose shape served as the original for the sign *sila,* meaning "litre." It is not too rash to deduce from the mass production of such standard vessels that they served for the issue of rations. This would have been the earliest instance of a system that remained typical of the southern Mesopotamian city for centuries: the maintenance of part of the population by allocations of food from the state.

Appearance of written sources

Historians usually date the beginning of history, as opposed to prehistory and protohistory, from the first appearance of usable written sources. If this is taken to be the transition from the 4th to the 3rd millennium BC, it must be remembered that this applies only to part of Mesopotamia: the south, the Diyālā region, Susiana (with a later script of its own invented locally), and the district of the middle Euphrates, as well as Iran.

SUMERIAN CIVILIZATION

The Sumerians to the end of the Early Dynastic period. Despite the Sumerians' leading role, the historical role of other races should not be underestimated. While with prehistory only approximate dates can be offered, historical periods require a firm chronological framework, which, unfortunately, has not yet been established for the first half of the 3rd millennium BC. The basis for the chronology after about 1450 BC is provided by the data in the Assyrian and Babylonian king lists, which can often be checked by dated tablets and the Assyrian lists of eponyms (annual officials whose names served to identify each year). It is, however, still uncertain how much time separated the middle of the 15th century BC from the end of the 1st dynasty of Babylon, which is therefore variously dated to 1594 BC ("middle"), 1530 BC ("short"), or 1730 BC ("long" chronology). As a compromise, the middle chronology is used here. From 1594 BC several chronologically overlapping dynasties reach back to the beginning of the 3rd dynasty of Ur, about 2112 BC. From this point to the beginning of the dynasty of Akkad (*c.* 2334 BC) the interval can only be calculated to within 40 to 50 years, via the ruling houses of Lagash and the rather uncertain traditions regarding the succession of Gutian viceroys. With Ur-Nanshe (*c.* 2520 BC), the first king of the 1st dynasty of Lagash, there is a possible variation of 70 to 80 years, and earlier dates are a matter of mere guesswork: they depend upon factors of only limited relevance, such as the computation of occupation or destruction levels, the degree of development in the script (paleography), the character of the sculpture, pottery, and cylinder seals, and their correlation at different sites. In short, the chronology of the first half of the 3rd millennium is largely a matter for the intuition of the individual author. Carbon-14 dates are at present too few and far between to be given undue weight. Consequently, the turn of the 4th to 3rd millennium is to be accepted, with due caution and reservations, as the date of the flourishing of the archaic civilization of Uruk and of the invention of writing.

In Uruk and probably also in other cities of comparable size, the Sumerians led a city life that can be more or less reconstructed as follows: temples and residential districts; intensive agriculture, stock breeding, fishing, and date palm cultivation forming the four mainstays of the economy; and highly specialized industries carried on by sculptors, seal engravers, smiths, carpenters, shipbuilders, potters, and workers of reeds and textiles. Part of the population was supported with rations from a central point of distribution, which relieved people of the necessity of providing their basic food themselves, in return for their work all day and every day, at least for most of the year. The cities kept up active trade with foreign lands.

Economic and administrative texts

That organized city life existed is demonstrated chiefly by the existence of inscribed tablets. The earliest tablets contain figures with the items they enumerate and measures with the items they measure, as well as personal names and, occasionally, probably professions. This shows the purely practical origins of writing in Mesopotamia: it began not as a means of magic or as a way for the ruler to record his achievements, for example, but as an aid to memory for an administration that was ever expanding its area of operations. The earliest examples of writing are very difficult to penetrate because of their extremely laconic formulation, which presupposes a knowledge of the context, and because of the still very imperfect rendering of the spoken word. Moreover, many of the archaic signs were pruned away after a short period of use and cannot be traced in the paleography of later periods, so that they cannot be identified.

One of the most important questions that has to be met when dealing with "organization" and "city life" is that of social structure and the form of government; however, it can be answered only with difficulty, and the use of evidence from later periods carries with it the danger of anachronisms. The Sumerian word for ruler par excellence is *lugal,* which etymologically means "big person." The first occurrence comes from Kish about 2700 BC, since an earlier instance from Uruk is uncertain because it could simply be intended as a personal name: "Monsieur Legrand." In Uruk the ruler's special title was *en.* In later periods this word (etymology unknown), which is also found in divine names such as Enlil and Enki, has a predominantly religious connotation that is translated, for want of a better designation, as "en-priest, en-priestess." *En,* as the ruler's title, is encountered in the traditional epics of the Sumerians (Gilgamesh is the "*en* of Kullab," a district of Uruk) and particularly in personal names, such as "The-*en*-has-abundance," "The-*en*-occupies-the-throne," and many others.

It has often been asked if the ruler of Uruk is to be recognized in artistic representations. A man feeding sheep with flowering branches, a prominent personality in seal designs, might thus represent the ruler or a priest in his capacity as administrator and protector of flocks. The same question may be posed in the case of a man who is depicted on a stela aiming an arrow at a lion. These questions are purely speculative, however: even if the "protector of flocks" were identical with the *en,* there is no ground for seeing in the ruler a person with a predominantly religious function.

Literary and other historical sources. The picture offered by the literary tradition of Mesopotamia is clearer but not necessarily historically relevant. The Sumerian king list has long been the greatest focus of interest. This is a literary composition, dating from Old Babylonian times, that describes kingship (*nam-lugal* in Sumerian) in Mesopotamia from primeval times to the end of the 1st dynasty of Isin. According to the theory—or rather the ideology—of this work, there was officially only one kingship in Mesopotamia, which was vested in one particular city at any one time; hence the change in dynasties brought with it the change of the seat of kingship:

The Sumerian king list

Kish–Uruk–Ur–Awan–Kish–Hamazi–Uruk–Ur–
Adab–Mari–Kish–Akshak–Kish–Uruk–Akkad–
Uruk–Gutians–Uruk–Ur–Isin.

The king list gives as coming in succession several dynasties that now are known to have ruled simultaneously. It is a welcome aid to chronology and history, but, so far as the regnal years are concerned, it loses its value for the time before the dynasty of Akkad, for here the lengths of reign of single rulers are given as more than 100 and sometimes even several hundred years. One group of versions of the king list has adopted the tradition of the Sumerian Flood

story, according to which Kish was the first seat of kingship after the Flood, whereas five dynasties of primeval kings ruled before the Flood in Eridu, Bad-tibira, Larak, Sippar, and Shuruppak. These kings all allegedly ruled for multiples of 3,600 years (the maximum being 64,800 or, according to one variant, 72,000 years). The tradition of the Sumerian king list is still echoed in Berosus.

It is also instructive to observe what the Sumerian king list does not mention. The list lacks all mention of a dynasty as important as the 1st dynasty of Lagash (from King Ur-Nanshe to UruKAgina) and appears to retain no memory of the archaic florescence of Uruk at the beginning of the 3rd millennium BC.

Besides the peaceful pursuits reflected in art and writing, the art also provides the first information about violent contacts: cylinder seals of the Uruk Level IV depict fettered men lying or squatting on the ground, being beaten with sticks or otherwise maltreated by standing figures. They may represent the execution of prisoners of war. It is not known from where these captives came or what form "war" would have taken or how early organized battles were fought. Nevertheless, this does give the first, albeit indirect, evidence for the wars that are henceforth one of the most characteristic phenomena in the history of Mesopotamia.

Early religious beliefs

Just as with the rule of man over man, with the rule of higher powers over man it is difficult to make any statements about the earliest attested forms of religion or about the deities and their names without running the risk of anachronism. Excluding prehistoric figurines, which provide no evidence for determining whether men or anthropomorphic gods are represented, the earliest testimony is supplied by certain symbols that later became the cuneiform signs for gods' names: the "gatepost with streamers" for Inanna, goddess of love and war, and the "ringed post" for the moon god Nanna. A scene on a cylinder seal—a shrine with an Inanna symbol and a "man" in a boat—could be an abbreviated illustration of a procession of gods or of a cultic journey by ship. The constant association of the "gatepost with streamers" with sheep and of the "ringed post" with cattle may possibly reflect the area of responsibility of each deity. The Sumerologist Thorkild Jacobsen sees in the pantheon a reflex of the various economies and modes of life in ancient Mesopotamia: fishermen and marsh dwellers, date palm cultivators, cowherds, shepherds, and farmers all have their special groups of gods.

Both Sumerian and non-Sumerian languages can be detected in the divine names and place-names. Since the pronunciation of the names is known only from 2000 BC or later, conclusions about their linguistic affinity are not without problems. Several names, for example, have been reinterpreted in Sumerian by popular etymology. It would be particularly important to isolate the Subarian components (related to Hurrian), whose significance was probably greater than has hitherto been assumed. For the south Mesopotamian city HA.A (the noncommittal transliteration of the signs) there is a pronunciation gloss "shubari," and non-Sumerian incantations are known in the language of HA.A that have turned out to be "Subarian."

There have always been in Mesopotamia speakers of Semitic languages (which belong to the Afro-Asiatic group and also include ancient Egyptian, Berber, and various African languages). This element is easier to detect in ancient Mesopotamia, but whether people began to participate in city civilization in the 4th millennium BC or only during the 3rd is unknown. Over the last 4,000 years, Semites (Amorites, Canaanites, Aramaeans, and Arabs) have been partly nomadic, ranging the Arabian fringes of the Fertile Crescent, and partly settled; and the transition to settled life can be observed in a constant, though uneven, rhythm. There are, therefore, good grounds for assuming that the Akkadians (and other pre-Akkadian Semitic tribes not known by name) also originally led a nomadic life to a greater or lesser degree. Nevertheless, they can only have been herders of domesticated sheep and goats, which require changes of pasturage according to the time of year and can never stray more than a day's march from the watering places. The traditional nomadic life of the Bedouin makes its appearance only with the domestication of the camel at the turn of the 2nd to 1st millennium BC.

The spread of writing

The question arises as to how quickly writing spread and by whom it was adopted in about 3000 BC or shortly thereafter. At Kish, in northern Babylonia, almost 120 miles northwest of Uruk, a stone tablet has been found with the same repertoire of archaic signs as those found at Uruk itself. This fact demonstrates that intellectual contacts existed between northern and southern Babylonia. The dispersion of writing in an unaltered form presupposes the existence of schools in various cities that worked according to the same principles and adhered to one and the same canonical repertoire of signs. It would be wrong to assume that Sumerian was spoken throughout the area in which writing had been adopted. Moreover, the use of cuneiform for a non-Sumerian language can be demonstrated with certainty from the 27th century BC.

First historical personalities. The specifically political events in Mesopotamia after the flourishing of the archaic culture of Uruk cannot be pinpointed. Not until about 2700 BC does the first historical personality appear—historical because his name, Enmebaragesi (Me-baragesi), was preserved in later tradition. It has been assumed, although the exact circumstances cannot be reconstructed, that there was a rather abrupt end to the high culture of Uruk Level IV. The reason for the assumption is a marked break in both artistic and architectural traditions: entirely new styles of cylinder seals were introduced; the great temples (if in fact they were temples) were abandoned, flouting the rule of a continuous tradition on religious sites, and on a new site a shrine was built on a terrace, which was to constitute the lowest stage of the later Eanna ziggurat. On the other hand, since the writing system developed organically and was continually refined by innovations and progressive reforms, it would be overhasty to assume a revolutionary change in the population.

In the quarter or third of a millennium between Uruk Level IV and Enmebaragesi, southern Mesopotamia became studded with a complex pattern of cities, many of which were the centres of small independent city-states, to judge from the situation in about the middle of the millennium. In these cities, the central point was the temple, sometimes encircled by an oval boundary wall (hence the term temple oval); but nonreligious buildings, such as palaces serving as the residences of the rulers, could also function as centres.

Enmebaragesi, king of Kish, is the oldest Mesopotamian ruler from whom there are authentic inscriptions. These are vase fragments, one of them found in the temple oval of Khafajah (Khafājī). In the Sumerian king list, Enmebaragesi is listed as the penultimate king of the 1st dynasty of Kish; a Sumerian poem, "Gilgamesh and Agga of Kish," describes the siege of Uruk by Agga, son of Enmebaragesi. The discovery of the original vase inscriptions was of great significance because it enabled scholars to ask with somewhat more justification whether Gilgamesh, the heroic figure of Mesopotamia who has entered world literature, was actually a historical personage. The indirect synchronism notwithstanding, the possibility exists that even remote antiquity knew its "Ninus" and its "Semiramis," figures onto which a rapidly fading historical memory projected all manner of deeds and adventures. Thus, though the historical tradition of the early 2nd millennium believes Gilgamesh to have been the builder of the oldest city wall of Uruk, such may not have been the case. The palace archives of Shuruppak (modern Tall Fa'rah, 125 miles southeast of Baghdad), dating presumably from shortly after 2600, contain a long list of divinities, including Gilgamesh and his father Lugalbanda. More recent tradition, on the other hand, knows Gilgamesh as judge of the nether world. However that may be, an armed conflict between two Mesopotamian cities such as Uruk and Kish would hardly have been unusual in a country whose energies were consumed, almost without interruption from 2500 to 1500 BC, by clashes between various separatist forces. The great "empires," after all, formed the exception, not the rule.

Gilgamesh

Emergent city-states. Kish must have played a major

role almost from the beginning. After 2500, southern Babylonian rulers, such as Mesannepada of Ur and Eannatum of Lagash, frequently called themselves king of Kish when laying claim to sovereignty over northern Babylonia. This does not agree with some recent histories in which Kish is represented as an archaic "empire." It is more likely to have figured as representative of the north, calling forth perhaps the same geographic connotation later evoked by "the land of Akkad."

Although the corpus of inscriptions grows richer both in geographic distribution and in point of chronology in the 27th and increasingly so in the 26th century, it is still impossible to find the key to a plausible historical account, and history cannot be written solely on the basis of archaeological findings. Unless clarified by written documents, such findings contain as many riddles as they seem to offer solutions. This applies even to as spectacular a discovery as that of the royal tombs of Ur with their hecatombs (large-scale sacrifices) of retainers who followed their king and queen to the grave, not to mention the elaborate funerary appointments with their inventory of tombs. It is only from about 2520 to the beginnings of the dynasty of Akkad that history can be written within a framework, with the aid of reports about the city-state of Lagash and its capital of Girsu and its relations with its neighbour and rival, Umma.

Sources for this are, on the one hand, an extensive corpus of inscriptions relating to nine rulers, telling of the buildings they constructed, of their institutions and wars, and, in the case of UruKAgina, of their "social" measures. On the other hand, there is the archive of some 1,200 tablets—insofar as these have been published—from the temple of Baba, the city goddess of Girsu, from the period of Lugalanda and UruKAgina (first half of the 24th century). For generations, Lagash and Umma contested the possession and agricultural usufruct of the fertile region of Gu'edena. To begin with, some two generations before Ur-Nanshe, Mesilim (another "king of Kish") had intervened as arbiter and possibly overlord in dictating to both states the course of the boundary between them, but this was not effective for long. After a prolonged struggle, Eannatum forced the ruler of Umma, by having him take an involved oath to six divinities, to desist from crossing the old border, a dike. The text that relates this event, with considerable literary elaboration, is found on the Stele of Vultures. These battles, favouring now one side, now the other, continued under Eannatum's successors, in particular Entemena, until, under UruKAgina, great damage was done to the land of Lagash and to its holy places. The enemy, Lugalzagesi, was vanquished in turn by Sargon of Akkad. The rivalry between Lagash and Umma, however, must not be considered in isolation. Other cities, too, are occasionally named as enemies, and the whole situation resembles the pattern of changing coalitions and short-lived alliances between cities of more recent times. Kish, Umma, and distant Mari on the middle Euphrates are listed together on one occasion as early as the time of Eannatum. For the most part, these battles were fought by infantry, although mention is also made of war chariots drawn by onagers (wild asses).

Intercity rivalry between Lagash and Umma

The lords of Lagash rarely fail to call themselves by the title of *ensi,* of as yet undetermined derivation; "city ruler," or "prince," are only approximate translations. Only seldom do they call themselves *lugal,* or "king," the title given the rulers of Umma in their own inscriptions. In all likelihood, these were local titles that were eventually converted, beginning perhaps with the kings of Akkad, into a hierarchy in which the *lugal* took precedence over the *ensi.*

Territorial states. More difficult than describing its external relations is the task of shedding light on the internal structure of a state like Lagash. For the first time, a state consisting of more than a city with its surrounding territory came into being, because aggressively minded rulers had managed to extend that territory until it comprised not only Girsu, the capital, and the cities of Lagash and Nina (Zurghul) but also many smaller localities and even a seaport, Guabba. Yet it is not clear to what extent the conquered regions were also integrated administratively. On one occasion UruKAgina used the formula "from the limits of Ningirsu [that is, the city god of Girsu] to the sea," having in mind a distance of up to 125 miles. It would be unwise to harbour any exaggerated notion of well-organized states exceeding that size.

For many years, scholarly views were conditioned by the concept of the Sumerian temple city, which was used to convey the idea of an organism whose ruler, as representative of his god, theoretically owned all land, privately held agricultural land being a rare exception. The concept of the temple city had its origin partly in the overinterpretation of a passage in the so-called reform texts of UruKAgina, that states "on the field of the *ensi* [or his wife and the crown prince], the city god Ningirsu [or the city goddess Baba and the divine couple's son]" had been "reinstated as owners." On the other hand, the statements in the archives of the temple of Baba in Girsu, dating from Lugalanda and UruKAgina, were held to be altogether representative. Here is a system of administration, directed by the *ensi*'s spouse or by a *sangu* (head steward of a temple), in which every economic process, including commerce, stands in a direct relationship to the temple: agriculture, vegetable gardening, tree farming, cattle raising and the processing of animal products, fishing, and the payment in merchandise of workers and employees.

Temple administration

The conclusion from this analogy proved to be dangerous because the archives of the temple of Baba provide information about only a portion of the total temple administration and that portion, furthermore, is limited in time. Understandably enough, the private sector, which of course was not controlled by the temple, is scarcely mentioned at all in these archives. The existence of such a sector is nevertheless documented by bills of sale for land purchases of the pre-Sargonic period and from various localities. Written in Sumerian as well as in Akkadian, they prove the existence of private land ownership or, in the opinion of some scholars, of lands predominantly held as undivided family property. Although a substantial part of the population was forced to work for the temple and drew its pay and board from it, it is not yet known whether it was year-round work.

It is probable, if unfortunate, that there will never exist a detailed and numerically accurate picture of the demographic structure of a Sumerian city. It is assumed that in the oldest cities the government was in a position to summon sections of the populace for the performance of public works. The construction of monumental buildings or the excavation of long and deep canals could be carried out only by means of such a levy. The large-scale employment of indentured persons and of slaves is of no concern in this context. Evidence of male slavery is fairly rare before Ur III, and even in Ur III and in the Old Babylonian period slave labour was never an economically relevant factor. It was different with female slaves. According to one document, the temple of Baba employed 188 such women; the temple of the goddess Nanshe employed 180, chiefly in grinding flour and in the textile industry, and this continued to be the case in later times. For accuracy's sake it should be added that the terms male slave and female slave are used here in the significance they possessed about 2000 and later, designating persons in bondage who were bought and sold and who could not acquire personal property through their labour. A distinction is made between captured slaves (prisoners of war and kidnapped persons) and others who had been sold.

In one inscription, Entemena of Lagash boasts of having "allowed the sons of Uruk, Larsa, and Bad-tibira to return to their mothers" and of having "restored them into the hands" of the respective city god or goddess. Read in the light of similar but more explicit statements of later date, this laconic formula represents the oldest known evidence of the fact that the ruler occasionally endeavoured to mitigate social injustices by means of a decree. Such decrees might refer to the suspension or complete cancellation of debts or to exemption from public works. Whereas a set of inscriptions of the last ruler from the 1st dynasty of Lagash, UruKAgina, has long been considered a prime document of social reform in the 3rd millennium, the designation "reform texts" is only partly justified. Reading between the lines, it is possible to discern that tensions had

Inscriptions of UruKAgina

arisen between the "palace"—the ruler's residence with its annex, administrative staff, and landed properties—and the "clergy"—that is, the stewards and priests of the temples. In seeming defiance of his own interests, UruKAgina, who in contrast to practically all of his predecessors lists no genealogy and has therefore been suspected of having been a usurper, defends the clergy, whose plight he describes somewhat tearfully.

If the foregoing passage about restoring the *ensi*'s fields to the divinity is interpreted carefully, it would follow that the situation of the temple was ameliorated and that palace lands were assigned to the priests. Along with these measures, which resemble the policies of a newcomer forced to lean on a specific party, are found others that do merit the designation of "measures taken toward the alleviation of social injustices"—for instance, the granting of delays in the payment of debts or their outright cancellation and the setting up of prohibitions to keep the economically or socially more powerful from forcing his inferior to sell his house, his ass's foal, and the like. Besides this, there were tariff regulations, such as newly established fees for weddings and burials, as well as the precise regulation of the food rations of garden workers.

These conditions, described on the basis of source materials from Girsu, may well have been paralleled elsewhere, but it is equally possible that other archives, yet to be found in other cities of pre-Sargonic southern Mesopotamia, may furnish entirely new historical aspects. At any rate, it is wiser to proceed cautiously, keeping to analysis and evaluation of the available material rather than making generalizations.

This, then, is the horizon of Mesopotamia shortly before the rise of the Akkadian empire. In Mari, writing was introduced at the latest about the mid-26th century BC, and from that time this city, situated on the middle Euphrates, forms an important centre of cuneiform civilization, especially in regard to its Semitic component. Ebla (and probably many other sites in ancient Syria) profited from the influence of Mari scribal schools. Reaching out across the Diyālā region and the Persian Gulf, Mesopotamian influences extended to Iran, where Susa is mentioned along with Elam and other, not yet localized, towns. In the west the Amanus Mountains were known, and under Lugalzagesi the "upper sea"—in other words, the Mediterranean—is mentioned for the first time. To the east the inscriptions of Ur-Nanshe of Lagash name the isle of Dilmun (modern Bahrain), which may have been even then a transshipment point for trade with the Oman coast and the Indus region, the Magan and Meluhha of more recent texts. Trade with Anatolia and Afghanistan was nothing new in the 3rd millennium, even if these regions are not yet listed by their names. It was the task of the Akkadian dynasty to unite within these boundaries a territory that transcended the dimensions of a state of the type represented by Lagash.

Sumer and Akkad from 2350 to 2000 BC. There are several reasons for taking the year 2350 as a turning point in the history of Mesopotamia. For the first time, an empire arose on Mesopotamian soil. The driving force of that empire was the Akkadians, so called after the city of Akkad, which Sargon chose for his capital (it has not yet been identified but was presumably located on the Euphrates between Sippar and Kish). The name Akkad became synonymous with a population group that stood side by side with the Sumerians. Southern Mesopotamia became known as the "land of Sumer and Akkad"; Akkadian became the name of a language; and the arts rose to new heights. However, even this turning point was not the first time the Akkadians had emerged in history. Semites—whether Akkadians or a Semitic language group that had settled before them—may have had a part in the urbanization that took place at the end of the 4th millennium. The earliest Akkadian names and words occur in written sources of the 27th century. The names of several Akkadian scribes are found in the archives of Tall Abū Ṣalābīkh, near Nippur in central Babylonia, synchronous with those of Shuruppak (shortly after 2600). The Sumerian king list places the 1st dynasty of Kish, together with a series of kings bearing Akkadian names, immediately after the Flood. In Mari the Akkadian language was probably written from the very beginning. Thus, the founders of the dynasty of Akkad were presumably members of a people who had been familiar for centuries with Mesopotamian culture in all its forms.

Rise of the Akkadian empire

Sargon's reign. According to the Sumerian king list, the first five rulers of Akkad (Sargon, Rimush, Manishtusu, Naram-Sin, and Shar-kali-sharri) ruled for a total of 142 years; Sargon alone ruled for 56. Although these figures cannot be checked, they are probably trustworthy, because the king list for Ur III, even if 250 years later, did transmit dates that proved to be accurate.

As stated in an annotation to his name in the king list, Sargon started out as a cupbearer to King Ur-Zababa of Kish. There is an Akkadian legend about Sargon, describing how he was exposed after birth, brought up by a gardener, and later beloved by the goddess Ishtar. Nevertheless, there are no historical data about his career. Yet it is feasible to assume that in his case a high court office served as springboard for a dynasty of his own. The original inscriptions of the kings of Akkad that have come down to posterity are brief, and their geographic distribution generally is more informative than is their content. The main sources for Sargon's reign, with its high points and catastrophes, are copies made by Old Babylonian scribes in Nippur from the very extensive originals that presumably had been kept there. They are in part Akkadian, in part bilingual Sumerian-Akkadian texts. According to these texts, Sargon fought against the Sumerian cities of southern Babylonia, threw down city walls, took prisoner 50 *ensi*s, and "cleansed his weapons in the sea." He is also said to have captured Lugalzagesi of Uruk, the former ruler of Umma, who had vigorously attacked UruKAgina in Lagash, forcing his neck under a yoke and leading him thus to the gate of the god Enlil at Nippur. "Citizens of Akkad" filled the offices of *ensi* from the "nether sea" (the Persian Gulf) upward, which was perhaps a device used by Sargon to further his dynastic aims. Aside from the 34 battles fought in the south, Sargon also tells of conquests in northern Mesopotamia: Mari, Tuttul on the Balīkh, where he venerated the god Dagan (Dagon), Ebla (Tall Mardīkh in Syria), the "cedar forest" (Amanus or Lebanon), and the "silver mountains"; battles in Elam and the foothills of the Zagros are mentioned. Sargon also relates that ships from Meluhha (Indus region), Magan (possibly the coast of Oman), and Dilmun (Bahrain) made fast in the port of Akkad.

Sargon's conquests

Impressive as they are at first sight, these reports have only a limited value because they cannot be arranged chronologically, and it is not known whether Sargon built a large empire. Akkadian tradition itself saw it in this light, however, and a learned treatise of the late 8th or the 7th century lists no fewer than 65 cities and lands belonging to that empire. Yet, even if Magan and Kapturu (Crete) are given as the eastern and western limits of the conquered territories, it is impossible to transpose this to the 3rd millennium.

Sargon appointed one of his daughters priestess of the moon god in Ur. She took the name of Enheduanna and was succeeded in the same office by Enmenanna, a daughter of Naram-Sin. Enheduanna must have been a very gifted woman; two Sumerian hymns by her have been preserved, and she is also said to have been instrumental in starting a collection of songs dedicated to the temples of Babylonia.

Sargon died at a very old age. The inscriptions, also preserved only in copies, of his son Rimush are full of reports about battles fought in Sumer and Iran, just as if there had never been a Sargonic empire. It is not known in detail how rigorously Akkad wished to control the cities to the south and how much freedom had been left to them; but they presumably clung tenaciously to their inherited local autonomy. From a practical point of view, it was probably in any case impossible to organize an empire that would embrace all Mesopotamia.

Since the reports (*i.e.*, copies of inscriptions) left by Manishtusu, Naram-Sin, and Shar-kali-sharri speak time and again of rebellions and victorious battles and since Rimush, Manishtusu, and Shar-kali-sharri are themselves

said to have died violent deaths, the problem of what remained of Akkad's greatness obtrudes. Wars and disturbances, the victory of one and the defeat of another, and even regicide constitute only some of the aspects suggested to us by the sources. Whenever they extended beyond the immediate Babylonian neighbourhood, the military campaigns of the Akkadian kings were dictated primarily by trade interests instead of being intended to serve the conquest and safeguarding of an empire. Akkad, or more precisely the king, needed merchandise, money, and gold in order to finance wars, buildings, and the system of administration that he had instituted.

On the other hand, the original inscriptions that have been found so far of a king like Naram-Sin are scattered at sites covering a distance of some 620 miles as the crow flies, following the Tigris downriver: Diyarbakır on the upper Tigris, Nineveh, Tall Birāk (Tell Brak) on the upper Khābūr River (which had an Akkadian fortress and garrison), Susa in Elam, as well as Marad, Puzrish-Dagan, Adab (Bismāyah), Nippur, Ur, and Girsu in Babylonia. Even if all this was not part of an empire, it surely constituted an impressive sphere of influence.

Also to be considered are other facts that weigh more heavily than high-sounding reports of victories that cannot be verified. After the first kings of the dynasty had borne the title of king of Kish, Naram-Sin assumed the title "king of the four quarters of the earth"—that is, of the universe. As if he were in fact divine, he also had his name written with the cuneiform sign "god," the divine determinative that was customarily used in front of the names of gods; furthermore, he assumed the title of "god of Akkad." It is legitimate to ask whether the concept of deification may be used in the sense of elevation to a rank equal to that of the gods. At the very least it must be acknowledged that, in relation to his city and his subjects, the king saw himself in the role played by the local divinity as protector of the city and guarantor of its well-being. In contemporary judicial documents from Nippur, the oath is often taken "by Naram-Sin," with a formula identical with that used in swearing by a divinity. Documents from Girsu contain Akkadian date formulas of the type "in the year in which Naram-Sin laid the foundations of the Enlil temple at Nippur and of the Inanna temple at Zabalam." As evidenced by the dating procedures customary in Ur III and in the Old Babylonian period, the use of such formulas presupposes that the respective city acknowledged as its overlord the ruler whose name is invoked.

Divine kingship

Ascendancy of Akkad. Under Akkad, the Akkadian language acquired a literary prestige that made it the equal of Sumerian. Under the influence, perhaps, of an Akkadian garrison at Susa, it spread beyond the borders of Mesopotamia. After having employed for several centuries an indigenous script patterned after cuneiform writing, Elam adopted Mesopotamian script during the Akkadian period and with a few exceptions used it even when writing in Elamite rather than Sumerian or Akkadian. The so-called Old Akkadian manner of writing is extraordinarily appealing from the aesthetic point of view; as late as the Old Babylonian era it served as a model for monumental inscriptions. Similarly, the plastic and graphic arts, especially sculpture in the round, relief work, and cylinder seals, reached a high point of perfection.

Thus the reign of the five kings of Akkad may be considered one of the most productive periods of Mesopotamian history. Although separatist forces opposed all unifying tendencies, Akkad brought about a broadening of political horizons and dimensions. The period of Akkad fascinated historiographers as did few other eras. Having contributed its share to the storehouse of legend, it has never disappeared from memory. With phrases such as "There will come a king of the four quarters of the earth," liver omens (soothsaying done by analyzing the shape of a sheep's liver) of the Old Babylonian period express the yearning for unity at a time when Babylonia had once again disintegrated into a dozen or more small states.

The end of the dynasty. Of the kings after Shar-kali-sharri (*c.* 2217–*c.* 2193), only the names and a few brief inscriptions have survived. Quarrels arose over the succession, and the dynasty went under, although modern scholars know as little about the individual stages of this decline as about the rise of Akkad. Two factors contributed to its downfall: the invasion of the nomadic Amurrus (Amorites), called Martu by the Sumerians, from the northwest, and the infiltration of the Gutians, who came, apparently, from the region between the Tigris and the Zagros Mountains to the east. This argument, however, may be a vicious circle, as these invasions were provoked and facilitated by the very weakness of Akkad. In Ur III the Amorites, in part already sedentary, formed one ethnic component along with Sumerians and Akkadians. The Gutians, on the other hand, played only a temporary role, even if the memory of a Gutian dynasty persisted until the end of the 17th century BC. As a matter of fact, the wholly negative opinion that even some modern historians have of the Gutians is based solely on a few stereotyped statements by the Sumerians and Akkadians, especially on the victory inscription of Utu-hegal of Uruk (*c.* 2116–*c.* 2110). While Old Babylonian sources give the region between the Tigris and the Zagros Mountains as the home of the Gutians, these people probably also lived on the middle Euphrates during the 3rd millennium. According to the Sumerian king list, the Gutians held the "kingship" in southern Mesopotamia for about 100 years. It has long been recognized that there is no question of a whole century of undivided Gutian rule and that some 50 years of this rule coincided with the final half century of Akkad. From this period there has also been preserved a record of a "Gutian interpreter." As it is altogether doubtful whether the Gutians had made any city of southern Mesopotamia their "capital" instead of controlling Babylonia more or less informally from outside, scholars cautiously refer to "viceroys" of this people. The Gutians have left no material records, and the original inscriptions about them are so scanty that no binding statements about them are possible.

The Gutians

The Gutians' influence probably did not extend beyond Umma. The neighbouring state of Lagash enjoyed a century of complete independence, between Shar-kali-sharri and the beginning of Ur III, during which time it showed expansionist tendencies and had widely ranging trade connections. Of the *ensi* Gudea, a contemporary of Ur-Nammu of Ur III, there are extant writings, exclusively Sumerian in language, which are of inestimable value. He had the time, power, and means to carry out an extensive program of temple construction during his reign, and in a hymn divided into two parts and preserved in two clay cylinders 12 inches (30 centimetres) high he describes explicitly the reconstruction of Eninnu, the temple of the god Ningirsu. Comprising 1,363 lines, the text is second in length only to Eannatum's Stele of Vultures among the literary works of the Sumerians up to that time. While Gudea forges a link, in his literary style, with his country's pre-Sargonic period, his work also bears the unmistakable stamp of the period of Akkad. Thus, the regions that furnish him building materials reflect the geographic horizon of the empire of Akkad, and the *ensi*'s title "god of his city" recalls the "god of Akkad" (Naram-Sin). The building hymn contains interesting particulars about the work force deployed. "Levies" were organized in various parts of the country, and the city of Girsu itself "followed the *ensi* as though it were a single man." Unfortunately lacking are synchronous administrative archives of sufficient length to provide less summarily compiled information about the social structure of Lagash at the beginning of the 3rd dynasty of Ur. After the great pre-Sargonic archives of the Baba temple at Girsu, only the various administrative archives of the kings of Ur III give a closer look at the functioning of a Mesopotamian state.

Gudea of Lagash

The 3rd dynasty of Ur. Utu-hegal of Uruk is given credit for having overthrown Gutian rule by vanquishing their king Tiriqan along with two generals. Utu-hegal calls himself lord of the four quarters of the earth in an inscription, but this title, adopted from Akkad, is more likely to signify political aspiration than actual rule. Utu-hegal was a brother of the Ur-Nammu who founded the 3rd dynasty of Ur ("3rd" because it is the third time that Ur is listed in the Sumerian king list). Under Ur-Nammu and his successors Shulgi, Amar-Su'ena, Shu-Sin, and Ibbi-Sin, this

dynasty lasted for a century (*c.* 2112–*c.* 2004). Ur-Nammu was at first "governor" of the city of Ur under Utu-hegal. How he became king is not known, but there may well be some parallels between his rise and the career of Ishbi-Erra of Isin or, indeed, that of Sargon. By eliminating the state of Lagash, Ur-Nammu caused the coveted overseas trade (Dilmun, Magan, and Meluhha) to flow through Ur. As evidenced by a new royal title that he was the first to bear—that of "king of Sumer and Akkad"—he had built up a state that comprised at least the southern part of Mesopotamia. Like all great rulers, he built much, including the very impressive ziggurats of Ur and Uruk, which acquired their final monumental dimensions in his reign.

The Code of Ur-Nammu

Assyriologists have given the name of Code of Ur-Nammu to a literary monument that is the oldest known example of a genre extending through the Code of Lipit-Ishtar in Sumerian to the Code of Hammurabi, written in Akkadian. (Some scholars have attributed it to Ur-Nammu's son Shulgi.) It is a collection of sentences or verdicts mostly following the pattern of "If A [assumption], it follows that B [legal consequence]." The collection is framed by a prologue and an epilogue. The original was most likely a stela, but all that is known of the Code of Ur-Nammu so far are Old Babylonian copies. The term code as used here is conventional terminology and should not give the impression of any kind of "codified" law; furthermore, the content of the Code of Ur-Nammu is not yet completely known. It deals, among other things, with adultery by a married woman, the defloration of someone else's female slave, divorce, false accusation, the escape of slaves, bodily injury, and the granting of security, as well as with legal cases arising from agriculture and irrigation.

Before its catastrophic end under Ibbi-Sin, the state of Ur III does not seem to have suffered setbacks and rebellions as grievous as those experienced by Akkad. There are no clear indications pointing to inner unrest, although it must be remembered that the first 20 years of Shulgi's reign are still hidden in darkness. However, from that point on until the beginning of Ibbi-Sin's reign, or for a period of 50 years at least, the sources give the impression of peace enjoyed by a country that lived undisturbed by encroachments from abroad. Some expeditions were sent into foreign lands, to the region bordering on the Zagros, to what later became Assyria, and to the vicinity of Elam, in order to secure the importation of raw materials, in a fashion reminiscent of Akkad. Force seems to have been employed only as a last resort, and every attempt was made to bring about peaceful conditions on the other side of the border through the dispatch of embassies or the establishment of family bonds—for example, by marrying the king's daughters to foreign rulers.

Shulgi, too, called himself king of the four quarters of the earth. Although he resided in Ur, another important centre was in Nippur, whence—according to the prevailing ideology—Enlil, the chief god in the Sumerian state pantheon, had bestowed on Shulgi the royal dignity. Shulgi and his successors enjoyed divine honours, as Naram-Sin of Akkad had before them; by now, however, the process of deification had taken on clearer outlines in that sacrifices were offered and chapels built to the king and his throne, while the royal determinative turned up in personal names. Along with an Utu-hegal ("The Sun God Is Exuberance") there appears a Shulgi-hegal ("Shulgi Is Exuberance"), and so forth.

Administration. The highest official of the state was the *sukkal-mah,* literally "supreme courier," whose position may be described as "(state) chancellor." The empire was divided into some 40 provinces ruled by as many *ensi*s, who, despite their far-reaching authority (civil administration and judicial powers), were no longer autonomous, even if only indirectly, although the office was occasionally handed down from father to son. They could not enter into alliances or wage wars on their own. The *ensi*s were appointed by the king and could probably also be transferred by him to other provinces. Each of these provinces was obliged to pay a yearly tribute, the amount of which was negotiated by emissaries. Of special significance in this

The *bala* system

was a system called *bala,* "cycle" or "rotation," in which the *ensi*s of the southern provinces took part; among other things, they had to keep the state stockyards supplied with sacrificial animals. Although the "province" often corresponded to a former city-state, many others were no doubt newly established. The so-called land-register text of Ur-Nammu describes four such provinces north of Nippur, giving the precise boundaries and ending in each case with the statement, "King Ur-Nammu has confirmed the field of the god XX for the god XX." In some cities, notably in Uruk, Mari, or Dēr (near Badrah, Iraq), the administration was in the hands of a *šakkana,* a man whose title is rendered partly by "governor" and partly by "general."

The available histories are practically unanimous in seeing in Ur III a strongly centralized state marked by the king's position as absolute ruler. Nevertheless, some caution is indicated. For one thing, the need to deal as carefully as possible with the *ensi*s must not be underestimated. A further question arises from the borders between and relative extent of the "public" and the "private" sector; the latter's importance may have been underrated as well. What is meant by "private" sector is a population group with land of its own and with revenues not directly granted by a temple or a "palace," such as by the king's or an *ensi*'s household. The traditional picture is derived from the sources, the state archives of Puzrish-Dagan, a gigantic "stockyard" situated outside the gates of Nippur, which supplied the city's temples with sacrificial animals but inevitably also comprised a major wool and leather industry; other such archives are those of Umma, Girsu, Nippur, and Ur. All these activities were overseen by a finely honed bureaucracy that stressed the use of official channels, efficient administration, and precise accounting. The various administrative organs communicated with one another by means of a smoothly functioning network of messengers. Although almost 24,000 documents referring to the economy of Ur III have so far been published, the majority of them are still waiting to be properly evaluated. Nor is there yet a serviceable typology for them; only when that has been drawn up will it be possible to write a book entitled "The Economic System of Ur III." Represented in the main by contracts (loans, leases of temple land, the purchase of slaves, and the like), the "private" sector makes up only a small part of this mass of textual material. Neither can the sites at which discoveries have been made so far be taken as representative. In northern Babylonia, for example, scarcely any contemporary written documents have yet been recovered.

Ethnic, geographic, and intellectual constituents. From the ethnic point of view, Mesopotamia was as heterogeneous at the end of the 3rd millennium as it had been earlier. The Akkadian element predominated, and the proportion of speakers of Akkadian to speakers of Sumerian continued to change in favour of the former. The third group, first mentioned under Shar-kali-sharri of Akkad, are the Amorites. In Ur III some members of this people are already found in the higher echelons of the administration, but most of them, organized in tribes, still led a nomadic life. Their great days came in the Old Babylonian period. While clearly differing linguistically from Akkadian, the Amorite language, which can be reconstructed to some extent from more than a thousand proper names, is fairly closely related to the so-called Canaanite branch of the Semitic languages, of which it may in fact represent an older form. The fact that King Shu-Sin had a regular wall built clear across the land, the "wall that keeps out the Tidnum" (the name of a tribe), shows how strong the pressure of the nomads was in the 21st century and what efforts were made to check their influx. The fourth major ethnic group was the Hurrians, who were especially important in northern Mesopotamia and in the vicinity of modern Kirkūk.

The Amorites

It is likely that the geographic horizon of the empire of Ur III did not materially exceed that of the empire of Akkad. No names of localities in the interior of Anatolia have been found, but there was much coming and going of messengers between Mesopotamia and Iran, far beyond Elam. There is also one mention of Gubla (Byblos) on the Mediterranean coast. Oddly enough, there is no evidence of any relations with Egypt, either in Ur III or in the Old Babylonian period. It is odd if no contacts existed

at the end of the 3rd millennium between the two great civilizations of the ancient Middle East.

Intellectual life at the time of Ur III must have been very active in the cultivation and transmission of older literature, as well as in new creations. Although its importance as a spoken tongue was slowly diminishing, Sumerian still flourished as a written language, a state of affairs that continued into the Old Babylonian period. As shown by the hymn to the deified king, new literary genres arose in Ur III. If Old Babylonian copies are any indication, the king's correspondence with leading officials was also of a high literary level.

In the long view, the 3rd dynasty of Ur did not survive in historical memory as vigorously as did Akkad. To be sure, Old Babylonian historiography speaks of Ur III as *bala-Šulgi,* the "(reigning) cycle of Shulgi"; however, there is nothing that would correspond to the epic poems about Sargon and Naram-Sin. The reason is not clear, but it is conceivable that the later, purely Akkadian population felt a closer identification with Akkad than with a state that to a large extent still made use of the Sumerian language.

Ur III in decline. The decline of Ur III is an event in Mesopotamian history that can be followed in greater detail than other stages of that history thanks to sources such as the royal correspondence, two elegies on the destruction of Ur and Sumer, and an archive from Isin

Ishbi-Erra

that shows how Ishbi-Erra, as usurper and king of Isin, eliminated his former overlord in Ur. Ibbi-Sin was waging war in Elam when an ambitious rival came forward in the person of Ishbi-Erra from Mari, presumably a general or high official. By emphasizing to the utmost the danger threatening from the Amorites, Ishbi-Erra urged the king to entrust to him the protection of the neighbouring cities of Isin and Nippur. Ishbi-Erra's demand came close to extortion, and his correspondence shows how skillfully he dealt with the Amorites and with individual *ensis*, some of whom soon went over to his side. Ishbi-Erra also took advantage of the depression that the king suffered because the god Enlil "hated him," a phrase presumably referring to bad omens resulting from the examination of sacrificed animals, on which procedure many rulers based their actions (or, as the case may be, their inaction). Ishbi-Erra fortified Isin and, in the 10th year of Ibbi-Sin's reign, began to employ his own dating formulas on documents, an act tantamount to a renunciation of loyalty. Ishbi-Erra, for his part, believed himself to be the favourite of Enlil, the more so as he ruled over Nippur, where the god had his sanctuary. In the end he claimed suzerainty over all of southern Mesopotamia, including Ur.

While Ishbi-Erra purposefully strengthened his domains, Ibbi-Sin continued for 14 more years to rule over a decreasing portion of the land. The end of Ur came about through a concatenation of misfortunes: A famine broke out, and Ur was besieged, taken, and destroyed by the invading Elamites and their allies among the Iranian tribes. Ibbi-Sin was led away captive, and no more was heard of him. The elegies record in moving fashion the unhappy end of Ur, the catastrophe that had been brought about by the wrath of Enlil.

THE OLD BABYLONIAN PERIOD

Isin and Larsa. During the collapse of Ur III, Ishbi-Erra established himself in Isin and founded a dynasty there that lasted from 2017 to 1794. His example was followed elsewhere by local rulers, as in Dēr, Eshnunna, Sippar, Kish, and Larsa. In many localities an urge was felt to imitate the model of Ur; Isin probably took over unchanged the administrative system of that state. Ishbi-Erra and his successors had themselves deified, as did one of the rulers of Dēr, on the Iranian border. For almost a century Isin predominated within the mosaic of states that were slowly reemerging. Overseas trade revived after Ishbi-Erra had driven out the Elamite garrison from Ur, and under his successor, Shu-ilishu, a statue of the moon god Nanna, the city god of Ur, was recovered from the Elamites, who had carried it off. Up to the reign of Lipit-Ishtar (*c.* 1934–*c.* 1924), the rulers of Isin so resembled those of Ur, as far as the king's assessment of himself in the hymns is

concerned, that it seems almost arbitrary to postulate a break between Ibbi-Sin and Ishbi-Erra. As a further example of continuity it might be added that the Code of Lipit-Ishtar stands exactly midway chronologically between the Code of Ur-Nammu and the Code of Hammurabi. Yet it is much closer to the former in language and especially in legal philosophy than to Hammurabi's compilation of judgments. For example, the Code of Lipit-Ishtar does not know the lex talionis ("an eye for an eye and a tooth for a tooth"), the guiding principle of Hammurabi's penal law.

The Code of Lipit-Ishtar

Political fragmentation. It is probable that the definitive separation from Ur III came about through changing components of the population, from "Sumerians and Akkadians" to "Akkadians and Amorites." An Old Babylonian liver omen states that "he of the steppes will enter, and chase out the one in the city." This is indeed an abbreviated formula for an event that took place more than once: the usurpation of the king's throne in the city by the "sheikh" of some Amorite tribe. These usurpations were regularly carried out as part of the respective tribes became settled, although this was not so in the case of Isin because the house of Ishbi-Erra came from Mari and was of Akkadian origin, to judge by the rulers' names. By the same linguistic token the dynasty of Larsa was Amorite. The fifth ruler of the latter dynasty, Gungunum (ruled *c.* 1932–*c.* 1906), conquered Ur and established himself as the equal and rival of Isin; at this stage—the end of the 20th century BC—if not before, Ur had certainly outlived itself. From Gungunum until the temporary unification of Mesopotamia under Hammurabi, the political picture was determined by the disintegration of the balance of power, by incessant vacillation of alliances, by the presumption of the various rulers, by the fear of encroachments by the Amorite nomads, and by increasingly wretched social conditions. The extensive archive of correspondence from the royal palace of Mari (*c.* 1810–1750) is the best source of information about the political and diplomatic game and its rules, whether honoured or broken; it covers treaties, the dispatch and reception of embassies, agreements about the integration of allied armies, espionage, and "situation reports" from "foreign" courts. Devoid of exaggeration or stylization, these letters, dealing as they do with everyday events, are preferable to the numerous royal inscriptions on buildings, even when the latter contain historical allusions.

Literary texts and increasing decentralization. Another indirect but far from negligible source for the political and socioeconomic situation in the 20th–18th centuries BC is the literature of omens. These are long compendiums in which the condition of a sheep's liver or some other divinatory object (for instance, the behaviour of a drop of oil in a beaker filled with water, the appearance of a newborn baby, and the shape of rising clouds of incense) is described at length and commented on with the appropriate prediction: "The king will kill his dignitaries and distribute their houses and property among the temples"; "A powerful man will ascend the throne in a foreign city"; "The land that rose up against its 'shepherd' will continue to be ruled by that 'shepherd' "; "The king will depose his chancellor"; and "They will lock the city gate and there will be a calamity in the city."

Omen texts

Beginning with Gungunum of Larsa, the texts allow greater insight into the private sector than in any other previous period. There is a considerable increase in the number of private contracts and private correspondences. Especially frequent among the private contracts are those concluded about loans of silver or grain (barley), illustrating the common man's plight, especially when driven to seek out a creditor, the first step on a road that in many instances led to ruin. The rate of interest, fixed at 20 percent in the case of silver and 33 percent in that of grain, increased further if the deadline for repayment, usually at harvest time, was not kept. Insolvency resulted in imprisonment for debt, slavery by mortgage, and even the sale of children and the debtor's own person. Many private letters contain entreaties for the release of family members from imprisonment at the creditor's hands. Yet considerable fortunes were also made, in "liquid" capital as well as landed property. As these tendencies threatened to end in economic disaster, the kings prescribed as a corrective the liquidation of debts, by way of temporary alleviation at least. The exact wording of one such decree is known from the time of Ammiṣaduqa of Babylon.

Until the Ur III period, the only archives so far recovered dealt with temples or the palace. However, belonging to the Old Babylonian period, along with documents pertaining to civil law, were an increasing number of administrative records of privately managed households, inns, and farms: settlements of accounts, receipts, and notes on various transactions. Here was clearly a regular bourgeoisie, disposing of its own land and possessing means independent of temple and palace. Trade, too, was now chiefly in private hands; the merchant traveled (or sent his partners) at his own risk, not on behalf of the state. Among the civil-law contracts there was a substantial increase in records of land purchases. Also significant for the economic situation in the Old Babylonian era was a process that might be summarized as "secularization of the temples," even if all the stages of this development cannot be traced. The palace had probably possessed for centuries the authority to dispose of temple property, but, whereas UruKAgina of Lagash had still branded the tendency as leading to abuses, the citizen's relationship to the temple now took on individual traits. Revenues from certain priestly offices—benefices, in other words—went to private individuals and were sold and inherited. The process had begun in Ur, where the king bestowed benefices, although the recipients could not own them. The archives of the "canonesses" of the sun god of Sippar furnish a particularly striking example of the fusion of religious service and private economic interest. These women, who lived in a convent called *gagûm*, came from the city's leading families and were not allowed to marry. With their property, consisting of land and silver, they engaged in a lively and remunerative business by granting loans and leasing out fields.

Changing relationship between religious institutions and individuals

The tendency toward decentralization had begun in the Old Babylonian period with Isin. It concluded with the 72-year reign of the house of Kudur-Mabuk in Larsa (*c.* 1834–*c.* 1763). Kudur-Mabuk, sheikh of the Amorite tribe of the Jamutbal, despite his Elamite name, helped his son Warad-Sin to secure the throne. This usurpation allowed Larsa, which had passed through a period of internal unrest, to flourish one more time. Under Warad-Sin and in the long reign of his brother Rim-Sin, large portions of southern Babylonia, including Nippur, were once again united in one state of Larsa in 1794. Larsa was conquered by Hammurabi in 1763.

Early history of Assyria. Strictly speaking, the use of the name "Assyria" for the period before the latter half of the 2nd millennium BC is anachronistic; Assyria—as against the city-state of Ashur—did not become an independent state until about 1400 BC. For convenience, however, the term is used throughout this section.

In contrast to southern Mesopotamia or the mid-Euphrates region (Mari), written sources in Assyria do not begin until very late, shortly before Ur III. By Assyria—a region that does not lend itself to precise geographic delineation—is understood the territory on the Tigris north of the river's passage through the mountains of the Jabal Ḥamrīn to a point north of Nineveh, as well as the area between Little and Great Zab (a tributary of the Tigris in northeast Iraq) and to the north of the latter. In the north, Assyria was later bordered by the mountain state of Urartu; to the east and southeast its neighbour was the region around ancient Nuzi (near modern Kirkūk, "Arrapchitis" [Arrapkha] of the Greeks). In the early 2nd millennium the main cities of this region were Ashur (160 miles north-northwest of modern Baghdad), the capital (synonymous with the city god and national divinity); Nineveh, lying opposite modern Mosul; and Urbilum, later Arbela (modern Irbīl, some 200 miles north of Baghdad).

In Assyria, inscriptions were composed in Akkadian from the beginning. Under Ur III, Ashur was a provincial capital. Assyria as a whole, however, is not likely to have been a permanently secured part of the empire, since two date formulas of Shulgi and Amar-Su'ena mention the destruction of Urbilum. Ideas of the population of Assyria in the 3rd millennium are necessarily very imprecise. It

is not known how long Semitic tribes had been settled there. The inhabitants of southern Mesopotamia called Assyria Shubir in Sumerian and Subartu in Akkadian; these names may point to a Subarean population that was related to the Hurrians. Gasur, the later Nuzi, belonged to the Akkadian language region about the year 2200 but was lost to the Hurrians in the first quarter of the 2nd millennium. The Assyrian dialect of Akkadian found in the beginning of the 2nd millennium differs strongly from the dialect of Babylonia. These two versions of the Akkadian language continue into the 1st millennium.

In contrast to the kings of southern Mesopotamia, the rulers of Ashur styled themselves not king but partly *iššiakum,* the Akkadian equivalent of the Sumerian word *ensi,* partly *rubā'um,* or "great one." Unfortunately, the rulers cannot be synchronized precisely with the kings of southern Mesopotamia before Shamshi-Adad I (*c.* 1813–*c.* 1781 BC). For instance, it has not yet been established just when Ilushuma's excursion toward the southeast, recorded in an inscription, actually took place. Ilushuma boasts of having freed of taxes the "Akkadians and their children." While he mentions the cities of Nippur and Ur, the other localities listed were situated in the region east of the Tigris. The event itself may have taken place in the reign of Ishme-Dagan of Isin (*c.* 1953–*c.* 1935 BC), although how far Ilushuma's words correspond to the truth cannot be checked. In the Babylonian texts, at any rate, no reference is made to Assyrian intervention. The whole problem of dating is aggravated by the fact that the Assyrians did not, unlike the Babylonians, use date formulas that often contain interesting historical details; instead, every year was designated by the name of a high official (eponymic dating). The conscious cultivation of an old tradition is mirrored in the fact that two rulers of 19th-century Assyria called themselves Sargon and Naram-Sin after famous models in the Akkadian dynasty.

Problems with the Assyrian chronology

Aside from the generally scarce reports on projected construction, there is at present no information about the city of Ashur and its surroundings. There exists, however, unexpectedly rewarding source material from the trading colonies of Ashur in Anatolia. The texts come mainly from Kanesh (modern Kültepe, near Kayseri, in Turkey) and from Hattusa (modern Boğazköy, Tur.), the later Hittite capital. In the 19th century BC three generations of Assyrian merchants engaged in a lively commodity trade (especially in textiles and metal) between the homeland and Anatolia, also taking part profitably in internal Anatolian trade. Like their contemporaries in southern Mesopotamia, they did business privately and at their own risk, living peacefully and occasionally intermarrying with the "Anatolians." As long as they paid taxes to the local rulers, the Assyrians were given a free hand.

Clearly these forays by Assyrian merchants led to some transplanting of Mesopotamian culture into Anatolia. Thus the Anatolians adopted cuneiform writing and used the Assyrian language. While this influence doubtless already affected the first Hittites arriving in Anatolia, a direct line from the period of these trading colonies to the Hittite empire cannot yet be traced.

From about 1813 to about 1781 Assyria was ruled by Shamshi-Adad I, a contemporary of Hammurabi and a personality in no way inferior to him. Shamshi-Adad's father—an Amorite, to judge by the name—had ruled near Mari. The son, not being of Assyrian origin, ascended the throne of Assyria as a foreigner and on a detour, as it were, after having spent some time as an exile in Babylonia. He had his two sons rule as viceroys, in Ekallātum on the Tigris and in Mari, respectively, until the older of the two, Ishme-Dagan, succeeded his father on the throne. Through the archive of correspondence in the palace at Mari, scholars are particularly well informed about Shamshi-Adad's reign and many aspects of his personality. Shamshi-Adad's state had a common border for some time with the Babylonia of Hammurabi. Soon after Shamshi-Adad's death, Mari broke away, regaining its independence under an Amorite dynasty that had been living there for generations; in the end, Hammurabi conquered and destroyed Mari. After Ishme-Dagan's death, Assyrian history is lost sight of for more than 100 years.

The Old Babylonian empire. *Political fortunes.* Hammurabi (*c.* 1792–*c.* 1750 BC) is surely the most impressive and by now the best-known figure of the ancient Middle East of the first half of the 2nd millennium BC. He owes his posthumous reputation to the great stela into which the Code of Hammurabi was carved and indirectly also to the fact that his dynasty has made the name of Babylon famous for all time. In much the same way in which pre-Sargonic Kish exemplified the non-Sumerian area north of Sumer and Akkad lent its name to a country and a language, Babylon became the symbol of the whole country that the Greeks called Babylonia. This term is used anachronistically by Assyriologists as a geographic concept in reference to the period before Hammurabi. Originally the city's name was probably Babilla, which was reinterpreted in popular etymology as Bāb-ili ("Gate of the God").

Hammurabi

The 1st dynasty of Babylon rose from insignificant beginnings. The history of the erstwhile province of Ur is traceable from about 1894 onward, when the Amorite Sumuabum came to power there. What is known of these events fits altogether into the modest proportions of the period when Mesopotamia was a mosaic of small states. Hammurabi played skillfully on the instrument of coalitions and became more powerful than his predecessors had been. Nonetheless, it was only in the 30th year of his reign, after his conquest of Larsa, that he gave concrete expression to the idea of ruling all of southern Mesopotamia by "strengthening the foundations of Sumer and Akkad," in the words of that year's dating formula. In the prologue to the Code of Hammurabi the king lists the following cities as belonging to his dominions: Eridu near Ur, Ur, Lagash and Girsu, Zabalam, Larsa, Uruk, Adab, Isin, Nippur, Keshi, Dilbat, Borsippa, Babylon itself, Kish, Malgium, Mashkan-shapir, Kutha, Sippar, Eshnunna in the Diyālā region, Mari, Tuttul on the lower Balīkh (a tributary of the Euphrates), and finally Ashur and Nineveh. This was on a scale reminiscent of Akkad or Ur III. Yet Ashur and Nineveh cannot have formed part of this empire for long because at the end of Hammurabi's reign mention is made again of wars against Subartu—that is, Assyria.

Under Hammurabi's son Samsuiluna (*c.* 1749–*c.* 1712 BC) the Babylonian empire greatly shrank in size. Following what had almost become a tradition, the south rose up in revolt. Larsa regained its autonomy for some time, and the walls of Ur, Uruk, and Larsa were leveled. Eshnunna, which evidently had also seceded, was vanquished about 1730. Later chronicles mention the existence of a state in the Sealand, with its own dynasty (by "Sealand" is understood the marshlands of southern Babylonia). Knowledge of this new dynasty is unfortunately very vague, only one of its kings being documented in contemporary texts. About 1741 Samsuiluna mentions the Kassites for the first time; about 1726 he constructed a stronghold, "Fort Samsuiluna," as a bulwark against them on the Diyālā near its confluence with the Tigris.

Like the Gutians before them, the Kassites were at first prevented from entering Babylonia and pushed into the mid-Euphrates region; there, in the kingdom of Khana (centred on Mari and Terqa, both below the junction with the Khābūr River), a king appears with the Kassite name of Kashtiliashu, who ruled toward the end of the Babylonian dynasty. From Khana the Kassites moved south in small groups, probably as harvest workers. After the Hittite invasion under Mursilis I, who is said to have dethroned the last king of Babylon, Samsuditana, in 1595, the Kassites assumed the royal power in Babylonia. So far, the contemporary sources do not mention this epoch, and the question remains unresolved as to how the Kassite rulers named in king lists mesh with the end of the 2nd millennium BC.

Babylonian law. The Code of Hammurabi is the most frequently cited cuneiform document in specialized literature. Its first scholarly publication in 1902 led to the development of a special branch of comparative jurisprudence, the study of cuneiform law. Following the division made by the first editor, Jean-Vincent Scheil, the Code of Hammurabi contains 280 judgments, or "paragraphs," on civil and criminal law, dealing in the main with cases

The Code of Hammurabi

from everyday life in such a manner that it becomes obvious that the "lawgiver" or compiler had no intention of covering all possible contingencies. In broad outline, the themes treated in the Code of Hammurabi are libel; corrupt administration of justice; theft, receiving stolen goods, robbery, looting, and burglary; murder, manslaughter, and bodily injury; abduction; judicature of tax lessees; liability for negligent damage to fields and crop damage caused by grazing cattle; illegal felling of palm trees; legal problems of trade enterprises, in particular, the relationship between the merchant and his employee traveling overland, and embezzlement of merchandise; trust monies; the proportion of interest to loan money; the legal position of the female publican; slavery and ransom, slavery for debt, runaway slaves, the sale and manumission of slaves, and the contesting of slave status; the rent of persons, animals, and ships and their respective tariffs, offenses committed by hired labourers, and the vicious bull; family law: the price of a bride, dowry, the married woman's property, wife and concubine, and the legal position of the respective issue, divorce, adoption, the wet nurse's contract, and inheritance; and the legal position of certain priestesses.

A similar if much shorter compendium of judgments, probably antedating that of Hammurabi by a generation or two, has been discovered in Eshnunna.

Hammurabi, who called his own work *dīnāt mīšarim,* or "verdicts of the just order," states in the epilogue that it was intended as legal aid for persons in search of advice. Whether these judgments were meant to have binding force in the sense of modern statutes, however, is a matter of controversy. The Code of Hammurabi differs in many respects from the Code of Lipit-Ishtar, which was written in Sumerian. Its most striking feature lies in the extraordinary severity of its penalties and in the principle of the lex talionis. The same attitude is reflected in various Old Babylonian contracts in which defaulters are threatened with bodily punishment. It is often said, and perhaps rightly so, that this severity, which so contrasts with Sumerian judicial tradition, can be traced back to the Amorite influence.

There is yet another way in which the Code of Hammurabi has given rise to much discussion. Many of its "paragraphs" vary according to whether the case concerns an *awīlum,* a *muškēnum,* or a *wardum.* A threefold division of the populace had been postulated on the basis of these distinctions. The *wardum* is the least problematic: he is the slave—that is, a person in bondage who could be bought and sold, unless he was able to regain his freedom under certain conditions as a debtor-slave. The *muškēnum* were, under King Hammurabi at least, persons employed by the palace who could be given land in usufruct without receiving it as property. *Awīlum* were the citizens who owned land in their own right and depended neither on the palace nor on the temple. As the Soviet scholar Igor M. Diakonov has pointed out, the distinction cannot have been very sharply drawn, because the classes *awīlum* and *muškēnum* are not mutually exclusive: a man in high palace office could fairly easily purchase land as private property, whereas the free citizen who got into debt as a result of a bad harvest or some other misfortune had one foot in the slave class. Still unanswered is the question as to which segment of the population could be conscripted to do public works, a term that included the levy in case of war.

Social categories

Ammiṣaduqa (*c.* 1646–*c.* 1626 BC) comes a century and a half after Hammurabi. His edict, already referred to, lists, among others, the following social and economic factors: private debts in silver and grain, if arising out of loans, were canceled; also canceled were back taxes that certain officials owed the palace and that had to be collected from the people; the female publican had to renounce the collection of outstanding debts in beer and barley and was, in turn, excused from paying amounts of silver and barley to the king; taxes on leased property were reduced; debt slaves who had formerly been free (as against slaves made over from debtor to creditor) were ransomed; and high officials were forbidden on pain of death to press those who held property in fee into harvest work by prepayment of wages. The phrase "because the king gave the land a just order" serves as a rationale for many of these instances. In contrast to the codes, about whose binding force there is much doubt, edicts such as those of Ammiṣaduqa had legal validity since there are references to the edicts of other kings in numerous legal documents of the Old Babylonian period.

Babylonian literature. The literature and the literary languages of Babylonia during the three centuries following Ur III deserve attention. When commenting on literary and historical texts such as the inscriptions of the kings of Akkad, it was pointed out that these were not originals but copies of Old Babylonian vintage. So far, such copies are the main source for Sumerian literature. Yet, while the Old Babylonian period witnessed the creation of much literature (royal hymns of the kings of Isin, Larsa, and Babylon and elegies), it was above all a time of intensive cultivation of traditional literature. The great Sumerian poems, whose origins or first written version, respectively, can now be traced back to about 2600, were copied again and again. After 2000, when Sumerian as a spoken language rapidly receded to isolated regions and eventually disappeared altogether, texts began to be translated, line by line, into Akkadian until there came to be bilingual versions. An important part of this, especially in the instructional program in schools, were the so-called lexicographical texts. Sumerian word lists are almost as old as cuneiform writing itself; they formed the perfect material for those learning to write. In the Old Babylonian period, the individual lexical entries were translated and often annotated with phonetic signs. This led to the creation of "dictionaries," the value of which to the modern philologist cannot be exaggerated. Since Sumerian had to be taught much more than before, regular "grammatical treatises" also came into being: so far as it was possible, in view of the radically different structures of the two languages, Sumerian pronouns, verb forms, and the like were translated into Akkadian, including entire "paradigms" of individual verbs.

Literary texts

In belles lettres, Sumerian still predominates, although there is no lack of Akkadian masterpieces, including the oldest Akkadian version of the epic of Gilgamesh. The very high prestige still enjoyed by Sumerian should not be underestimated, and it continued to be used for inscriptions on buildings and the yearly dating formulas. Aside from being the language of practical affairs (*i.e.,* letters and contracts), there was a high incidence of Akkadian in soothsaying and divinatory literature. To be sure, the Sumerians also practiced foretelling the future from the examination of animal entrails, but as far as is known they did not write down the results. In Akkadian, on the other hand, there are extensive and "scientifically" arranged compendiums of omens based on the liver (as well as other omens), reflecting the importance that the divination of the future had in religion, in politics, and in all aspects of daily life.

Judging by its increasingly refined juridical thought, its ability to master in writing ever more complicated administrative procedures, its advanced knowledge of mathematics, and the fact that it marks the beginning of the study of astronomy, the Old Babylonian period appears to have been a time of exceedingly active intellectual endeavour—despite, if not because of, its lack of political cohesiveness.

The Hurrians. The Hurrians enter the orbit of ancient Middle Eastern civilization toward the end of the 3rd millennium BC. They arrived in Mesopotamia from the north or the east, but it is not known how long they had lived in the peripheral regions. There is a brief inscription in Hurrian language from the end of the period of Akkad, while that of King Arishen (or Atalshen) of Urkish and Nawar is written in Akkadian. The language of the Hurrians must have belonged to a widespread group of ancient Middle Eastern languages. The relationship between Hurrian and Subarean has already been mentioned, and the language of the Urartians, who played an important role from the end of the 2nd millennium to the 8th century BC, is likewise closely related to Hurrian. According to the Soviet scholars Igor M. Diakonov and Sergei A. Starostin, the Eastern Caucasian languages are an offshoot of the Hurrian-Urartian group.

It is not known whether the migrations of the Hurrians ever took the form of aggressive invasion; 18th-century-BC texts from Mari speak of battles with the Hurrian tribe of Turukku south of Lake Urmia (some 150 miles from the Caspian Sea's southwest corner), but these were mountain campaigns, not the warding off of an offensive. Proper names in cuneiform texts, their frequency increasing in the period of Ur III, constitute the chief evidence for the presence of Hurrians. Nevertheless, there is no clear indication that the Hurrians had already advanced west of the Tigris at that time. An entirely different picture results from the 18th-century palace archives of Mari and from texts originating near the upper Khābūr River. Northern Mesopotamia, west of the Tigris, and Syria appear settled by a population that is mainly Amorite and Hurrian; and the latter had already reached the Mediterranean littoral, as shown by texts from Alalakh on the Orontes. In Mari, literary texts in Hurrian also have been found, indicating that Hurrian had by then become a fully developed written language as well.

The high point of the Hurrian period was not reached until about the middle of the 2nd millennium. In the 15th century, Alalakh was heavily Hurrianized; and in the empire of Mitanni the Hurrians represented the leading and perhaps the most numerous population group. (D.O.E.)

Mesopotamia to the end of the Achaemenian period

THE KASSITES, THE MITANNI, AND THE RISE OF ASSYRIA

About 150 years after the death of Hammurabi, his dynasty was destroyed by an invasion of new peoples. Because there are very few written records from this era, the time from about 1560 BC to about 1440 BC (in some areas until 1400 BC) is called the dark ages. The remaining Semitic states, such as the state of Ashur, became minor states within the sphere of influence of the new states of the Kassites and the Hurrians/Mitanni. The languages of the older cultures, Akkadian and Sumerian, continued or were soon reestablished, however. The cuneiform script persisted as the only type of writing in the entire area. Cultural continuity was not broken off, either, particularly in Babylonia. A matter of importance was the emergence of new Semitic leading classes from the ranks of the priesthood and the scribes. These gained increasing power.

The dark ages

The Kassites in Babylonia. The Kassites had settled by 1800 BC in what is now western Iran in the region of Hamadan-Kermanshah. The first to feel their forward thrust was Samsuiluna, who had to repel groups of Kassite invaders. Increasing numbers of Kassites gradually reached Babylonia and other parts of Mesopotamia. There they founded principalities, of which little is known. No inscription or document in the Kassite language has been preserved. Some 300 Kassite words have been found in Babylonian documents. Nor is much known about the social structure of the Kassites or their culture. There seems to have been no hereditary kingdom. Their religion was polytheistic; the names of some 30 gods are known.

The beginning of Kassite rule in Babylonia cannot be dated exactly. A king called Agum II ruled over a state that stretched from western Iran to the middle part of the Euphrates valley; 24 years after the Hittites had carried off the statue of the Babylonian god Marduk, he regained possession of the statue, brought it back to Babylon, and renewed the cult, making the god Marduk the equal of the corresponding Kassite god, Shuqamuna. Meanwhile, native princes continued to reign in southern Babylonia. It may have been Ulamburiash who finally annexed this area around 1450 and began negotiations with Egypt in Syria. Karaindash built a temple with bas-relief tile ornaments in Uruk (Erech) around 1420. A new capital west of Baghdad, Dūr Kurigalzu, competing with Babylon, was founded and named after Kurigalzu I (*c.* 1400–*c.* 1375). His successors Kadashman-Enlil I (*c.* 1375–*c.* 1360) and Burnaburiash II (*c.* 1360–*c.* 1333) were in correspondence with the Egyptian rulers Amenhotep III and Akhenaton (Amenhotep IV). They were interested in trading their lapis lazuli and other items for gold as well as in planning political marriages. Kurigalzu II (*c.* 1332–*c.* 1308) fought against the Assyrians but was defeated by them. His successors sought to ally themselves with the Hittites in order to stop the expansion of the Assyrians. During the reign of Kashtiliash IV (*c.* 1232–*c.* 1225), Babylonia waged war on two fronts at the same time—against Elam and Assyria—ending in the catastrophic invasion and destruction of Babylon by Tukulti-Ninurta I. Not until the time of the kings Adad-shum-uṣur (*c.* 1216–*c.* 1187) and Melishipak (*c.* 1186–*c.* 1172) was Babylon able to experience a period of prosperity and peace. Their successors were again forced to fight, facing the conqueror King Shutruk-Nahhunte of Elam (*c.* 1185–*c.* 1155). Cruel and fierce, the Elamites finally destroyed the dynasty of the Kassites during these wars (about 1155). Some poetical works lament this catastrophe.

Society under the Kassites

Letters and documents of the time after 1380 show that many things had changed after the Kassites took power. The Kassite upper class, always a small minority, had been largely "Babylonianized." Babylonian names were to be found even among the royalty, and they predominated among the civil servants and the officers. The new feudal character of the social structure showed the influence of the Kassites. Babylonian town life had revived on the basis of commerce and handicrafts. The Kassitic nobility, however, maintained the upper hand in the rural areas, their wealthiest representatives holding very large landed estates. Many of these holdings came from donations of the king to deserving officers and civil servants, considerable privileges being connected with such grants. From the time of Kurigalzu II these were registered on stone tablets or, more frequently, on boundary stones called *kudurrus*. After 1200 the number of these increased substantially, because the kings needed a steadily growing retinue of loyal followers. The boundary stones had pictures in bas-relief, very often a multitude of religious symbols, and frequently contained detailed inscriptions giving the borders of the particular estate; sometimes the deserts of the recipient were listed and his privileges recorded; finally, trespassers were threatened with the most terrifying curses. Agriculture and cattle husbandry were the main pursuits on these estates, and horses were raised for the light war chariots of the cavalry. There was an export trade in horses and vehicles in exchange for raw material. As for the king, the idea of the social-minded ruler continued to be valid.

The decline of Babylonian culture at the end of the Old Babylonian period continued for some time under the Kassites. Not until approximately 1420 did the Kassites develop a distinctive style in architecture and sculpture. Kurigalzu I played an important part, especially in Ur, as a patron of the building arts. Poetry and scientific literature developed only gradually after 1400. The existence of earlier work is clear from poetry, philological lists, and collections of omens and signs that were in existence by the 14th century or before and that have been discovered in the Hittite capital of Hattusa, in the Syrian capital of Ugarit, and even as far away as Palestine. Somewhat later, new writings appear: medical diagnoses and recipes, more Sumero-Akkadian word lists, and collections of astrological and other omens and signs with their interpretations. Most of these works are known today only from copies of more recent date. The most important is the Babylonian epic of the creation of the world, *Enuma elish*. Composed by an unknown poet, probably in the 14th century, it tells the story of the god Marduk. He began as the god of Babylon and was elevated to be king over all other gods after having successfully accomplished the destruction of the powers of chaos. For almost 1,000 years this epic was recited during the New Year's festival in the spring as part of the Marduk cult in Babylon. The literature of this time contains very few Kassitic words. Many scholars believe that the essential groundwork for the development of the subsequent Babylonian culture was laid during the later epoch of the Kassite era.

The Hurrian and Mitanni kingdoms. The weakening of the Semitic states in Mesopotamia after 1550 enabled the Hurrians to penetrate deeper into this region, where they founded numerous small states in the eastern parts of Anatolia, Mesopotamia, and Syria. The Hurrians came from northwestern Iran, but until recently very little was known

Possible Aryan influences

about their early history. After 1500, isolated dynasties appeared with Indo-Aryan names, but the significance of this is disputed. The presence of Old Indian technical terms in later records about horse breeding and the use of the names of Indian gods (such as, for example, Indra and Varuna) in some compacts of state formerly led several scholars to assume that numerous groups of Aryans, closely related to the Indians, pushed into Anatolia from the northeast. They were also credited with the introduction of the light war chariot with spoked wheels. This conclusion, however, is by no means established fact. So far it has not been possible to appraise the numbers and the political and cultural influence of the Aryans in Anatolia and Mesopotamia relative to those of the Hurrians.

Some time after 1500 the kingdom of Mitanni (or Mittani) arose near the sources of the Khābūr River in Mesopotamia. Since no record or inscription of their kings has been unearthed, little is known about the development and history of the Mitanni kingdom before King Tushratta. The Mitanni empire was known to the Egyptians under the name of Naharina, and Thutmose III fought frequently against it after 1460 BC. By 1420 the domain of the Mitanni king Saustatar (Saushatar) stretched from the Mediterranean all the way to the northern Zagros Mountains, in western Iran, including Alalakh, in northern Syria, as well as Nuzi, Kurrukhanni, and Arrapkha. The northern boundary dividing Mitanni from the Hittites and the other Hurrian states was never fixed, even under Saustatar's successors Artatama I and Shuttarna II, who married their daughters to the pharaohs Thutmose IV (1400–1390) and Amenhotep III (1390–1353). Tushratta (*c.* 1365–*c.* 1330), the son of Shuttarna, was able to maintain the kingdom he had inherited for many years. In his sometimes very long letters—one of them written in Hurrian—to Amenhotep III and Akhenaton (1353–1336), he wrote about commerce, his desire for gold, and marriage. Weakened by internal strife, the Mitanni kingdom eventually became a pawn between the rising kingdoms of the Hittites and the Assyrians.

The kingdom of Mitanni was a feudal state led by a warrior nobility of Aryan or Hurrian origin. Frequently horses were bred on their large landed estates. Documents and contract agreements in Syria often mention a chariot-warrior caste that also constituted the social upper class in the cities. The aristocratic families usually received their landed property as an inalienable fief. Consequently, no documents on the selling of landed property are to be found in the great archives of Akkadian documents and letters discovered in Nuzi, near Kirkūk. The prohibition against selling landed property was often dodged, however, with a stratagem: the previous owner "adopted" a willing buyer against an appropriate sum of money. The wealthy lord Tehiptilla was "adopted" almost 200 times, acquiring tremendous holdings of landed property in this way without interference by the local governmental authorities. He had gained his wealth through trade and commerce and through a productive two-field system of agriculture (in which each field was cultivated only once in two years). For a long time, Prince Shilwa-Teshub was in charge of the royal governmental administration in the district capital. Sheep breeding was the basis for a woolen industry, and textiles collected by the palace were exported on a large scale. Society was highly structured in classes, ranks, and professions. The judiciary, patterned after the Babylonian model, was well organized; the documents place heavy emphasis on correct procedure.

Hurrian religion

Native sources on the religion of the Hurrians of the Mitanni kingdom are limited; about their mythology, however, much is known from related Hittite and Ugaritic myths. Like the other peoples of the ancient Middle East, the Hurrians worshiped gods of various origins. The king of the gods was the weather god Teshub. According to the myths, he violently deposed his father Kumarbi; in this respect he resembled the Greek god Zeus, who deposed his father Kronos. The war chariot of Teshub was drawn by the bull gods Seris ("Day") and Hurris ("Night"). Major sanctuaries of Teshub were located at Arrapkha (modern Kirkūk) and at Halab (modern Aleppo) in Syria. In the east his consort was the goddess of love and war Shaushka, and in the west the goddess Hebat (Hepat); both were similar to the Ishtar-Astarte of the Semites.

The sun god Shimegi and the moon god Kushuh, whose consort was Nikkal, the Ningal of the Sumerians, were of lesser rank. More important was the position of the Babylonian god of war and the underworld, Nergal. In northern Syria the god of war Astapi and the goddess of oaths Ishara are attested as early as the 3rd millennium BC.

In addition, a considerable importance was attributed to impersonal numina such as heaven and earth as well as to deities of mountains and rivers. In the myths the terrible aspect of the gods often prevails over indications of a benevolent attitude. The cults of sacrifices and other rites are similar to those known from the neighbouring countries; many Hurrian rituals were found in Hittite Anatolia. There is abundant evidence for magic and oracles.

Temple monuments of modest dimensions have been unearthed; in all probability, specific local traditions were a factor in their design. The dead were probably buried outside the settlement. Small artifacts, particularly seals, show a peculiar continuation of Babylonian and Assyrian traditions in their preference for the naturalistic representation of figures. There were painted ceramics with finely drawn decorations (white on a dark background). The strong position of the royal house was evident in the large palaces, existing even in district capitals. The palaces were decorated with frescoes. Because only a few Mitanni settlements have been unearthed in Mesopotamia, knowledge of Mitanni arts and culture is as yet insufficient.

Assyria under Mitanni rule

The rise of Assyria. Very little can be said about northern Assyria during the 2nd millennium BC. Information on the old capital, Ashur, located in the south of the country, is somewhat more plentiful. The old lists of kings suggest that the same dynasty ruled continuously over Ashur from about 1600. All the names of the kings are given, but little else is known about Ashur before 1420. Almost all the princes had Akkadian names, and it can be assumed that their sphere of influence was rather small. Although Assyria belonged to the kingdom of the Mitanni for a long time, it seems that Ashur retained a certain autonomy. Located close to the boundary with Babylonia, it played that empire off against Mitanni whenever possible. Puzur-Ashur III concluded a border treaty with Babylonia about 1480, as did Ashur-bel-nisheshu about 1405. Ashur-nadin-ahhe II (*c.* 1392–*c.* 1383) was even able to obtain support from Egypt, which sent him a consignment of gold.

Ashur-uballiṭ I (*c.* 1354–*c.* 1318) was at first subject to King Tushratta of Mitanni. After 1340, however, he attacked Tushratta, presumably together with Suppiluliumas I of the Hittites. Taking away from Mitanni parts of northeastern Mesopotamia, Ashur-uballiṭ now called himself "Great King" and socialized with the king of Egypt on equal terms, arousing the indignation of the king of Babylonia. Ashur-uballiṭ was the first to name Assyria the Land of Ashur, because the old name, Subartu, was often used in a derogatory sense in Babylonia. He ordered his short inscriptions to be partly written in the Babylonian dialect rather than the Assyrian, since this was considered refined. Marrying his daughter to a Babylonian, he intervened there energetically when Kassite nobles murdered his grandson. Future generations came to consider him rightfully as the real founder of the Assyrian empire. His son Enlil-nirari (*c.* 1326–*c.* 1318) also fought against Babylonia. Arik-den-ili (*c.* 1308–*c.* 1297) turned westward, where he encountered Semitic tribes of the so-called Akhlamu group.

Still greater successes were achieved by Adad-nirari I (*c.* 1295–*c.* 1264). Defeating the Kassite king Nazimaruttash, he forced him to retreat. After that he defeated the kings of Mitanni, first Shattuara I, then Wasashatta. This enabled him for a time to incorporate all Mesopotamia into his empire as a province, although in later struggles he lost large parts to the Hittites. In the east, he was satisfied with the defense of his lands against the mountain tribes.

Adad-nirari's inscriptions were more elaborate than those of his predecessors and were written in the Babylonian dialect. In them he declares that he feels called to these wars by the gods, a statement that was to be repeated by other kings after him. Assuming the old title of great king, he

called himself "King of All." He enlarged the temple and the palace in Ashur and also developed the fortifications there, particularly at the banks of the Tigris River. He worked on large building projects in the provinces.

Shalmaneser I

His son Shalmaneser I (Shulmanu-asharidu; *c.* 1263–*c.* 1234) attacked Uruatru (later called Urartu) in southern Armenia, which had allegedly broken away. Shattuara II of Hanigalbat, however, put him into a difficult situation, cutting his forces off from their water supplies. With courage born of despair, the Assyrians fought themselves free. They then set about reducing what was left of the Mitanni kingdom into an Assyrian province. The king claimed to have blinded 14,400 enemies in one eye—psychological warfare of a similar kind was used more and more as time went by. The Hittites tried in vain to save Hanigalbat. Together with the Babylonians they fought a commercial war against Ashur for many years. Like his father, Shalmaneser was a great builder. At the juncture of the Tigris and Great Zab rivers, he founded a strategically situated second capital, Kalakh (biblical Calah; modern Nimrūd).

His son was Tukulti-Ninurta (*c.* 1233–*c.* 1197), the Ninus of Greek legends. Gifted but extravagant, he made his nation a great power. He carried off thousands of Hittites from eastern Anatolia. He fought particularly hard against Babylonia, deporting Kashtiliash IV to Assyria. When the Babylonians rebelled again, he plundered the temples in Babylon, an act regarded as a sacrilege, even in Assyria. The relationship between the king and his capital deteriorated steadily. For this reason the king began to build a new city, Kar-Tukulti-Ninurta, on the other side of the Tigris River. Ultimately, even his sons rebelled against him and laid siege to him in his city; in the end he was murdered. His victorious wars against Babylonia were glorified in an epic poem, but his empire broke up soon after his death. Assyrian power declined for a time, while that of Babylonia rose.

Assyria had suffered under the oppression of both the Hurrians and the Mitanni kingdom. Its struggle for liberation and the bitter wars that followed had much to do with its development into a military power. In his capital of Ashur, the king depended on the citizen class and the priesthood, as well as on the landed nobility that furnished him with the war-chariot troops.

Documents and letters show the important role that agriculture played in the development of the state. Assyria was less dependent on artificial irrigation than was Babylonia. The breeding of horses was carried on intensively; remnants of elaborate directions for their training are extant. Trade and commerce also were of notable significance: metals were imported from Anatolia or Armenia, tin from northwestern Iran, and lumber from the west. The opening up of new trade routes was often a cause and the purpose of war.

Artistic and cultural developments

Assyrian architecture, derived from a combination of Mitannian and Babylonian influences, developed early quite an individual style. The palaces often had colourful wall decorations. The art of seal cutting, taken largely from Mitanni, continued creatively on its own. The schools for scribes, where all the civil servants were trained, taught both the Babylonian and the Assyrian dialects of the Akkadian language. Babylonian works of literature were assimilated into Assyrian, often reworked into a different form. The Hurrian tradition remained strong in the military and political sphere while at the same time influencing the vocabulary of language.

ASSYRIA AND BABYLONIA AT THE END OF THE 2ND MILLENNIUM

Babylonia under the 2nd dynasty of Isin. In a series of heavy wars about which not much is known, Marduk-kabit-ahheshu (*c.* 1152–*c.* 1135) established what came to be known as the 2nd dynasty of Isin. His successors were often forced to continue the fighting. The most famous king of the dynasty was Nebuchadrezzar I (Nabu-kudurri-uṣur; *c.* 1119–*c.* 1098). He fought mainly against Elam, which had conquered and ravaged a large part of Babylonia. His first attack miscarried because of an epidemic among his troops, but in a later campaign he conquered Susa, the capital of Elam, and returned the previously removed statue of the god Marduk to its proper place. Soon thereafter the king of Elam was assassinated, and his kingdom once again fell apart into small states. This enabled Nebuchadrezzar to turn west, using the later years of peace to start extensive building projects. After him, his son became king, succeeded by his brother Marduk-nadin-ahhe (*c.* 1093–*c.* 1076). At first successful in his wars against Assyria, he later experienced heavy defeat. A famine of catastrophic proportions triggered an attack from Aramaean tribes, the ultimate blow. His successors made peace with Assyria, but the country suffered more and more from repeated attacks by Aramaeans and other Semitic nomads. Even though some of the kings still assumed grand titles, they were unable to stem the progressive disintegration of their empire. There followed the era known as the 2nd dynasty of the Sealand (*c.* 1020–*c.* 1000), which included three usurpers. The first of these had the Kassitic name of Simbar-Shihu (or Simbar-Shipak; *c.* 1020–*c.* 1003).

Toward the end of its reign, the dynasty of the Kassites became completely Babylonianized. The changeover to the dynasty of Isin, actually a succession of kings from different families, brought no essential transformation of the social structure. The feudal order remained. New landed estates came into existence in many places through grants to deserving officers; many boundary stones (*kudurrus*) have been found that describe them. The cities of Babylonia retained much of their former autonomy. The border provinces, however, were administered by royally appointed governors with civil and military functions.

In the literary arts this was a period of creativity; thus the later Babylonians with good reason regarded the time of Nebuchadrezzar I as one of the great eras of their history. A heroic epic, modeled upon older epics, celebrates the deeds of Nebuchadrezzar I, but unfortunately little of it is extant. Other material comes from the ancient myths. The poet of the later version of the epic of Gilgamesh, Sin-leqe-unnini (*c.* 1150–?) of Uruk, is known by name. This version of the epic is known as the Twelve-Tablet Poem; it contains about 3,000 verses. It is distinguished by its greater emphasis on the human qualities of Gilgamesh and his friend Enkidu; this quality makes it one of the great works of world literature.

The epic of Gilgamesh

Another poet active at about the same time was the author of a poem of 480 verses called *Ludlul bēl nēmeqi* ("Let Me Praise the Possessor of Wisdom"). The poem meditates on the workings of divine justice, which sometimes appear strange and inexplicable to suffering human beings; this subject had acquired an increasing importance in the contemporary religion of Babylon. The poem describes the multifarious sufferings of a high official and his subsequent salvation by the god Marduk.

The gradual reduction of the Sumerian pantheon of about 2,000 gods by the identification and integration of originally distinct gods and goddesses of similar functions resulted in a growing number of surnames or compound names for the main gods (Marduk, for example, had about 50 such names) and later in a conception of "the god" and "the goddess" with interchangeable names in the cults of the great temples. There was a theology of identifications of gods, which was documented by god lists in two columns with hundreds of entries in the form "Enzag = Nabû of (the island of) Dilmun," as well as by many hymns and prayers of the time and by later compositions.

As a consequence of the distinction of an enormous number of multifarious sins, the concept of a universal sinfulness of mankind is increasingly observed in this period and later. All human beings, therefore, were believed to be in need of the forgiveness afforded by the deities to sincere worshipers. Outside of Israel, the concept of sinfulness can be found in ancient times only in Babylonia and Assyria.

Assyria between 1200 and 1000 BC. After a period of decline following Tukulti-Ninurta I, Assyria was consolidated and stabilized under Ashur-dan I (*c.* 1179–*c.* 1134) and Ashur-resh-ishi I (*c.* 1133–*c.* 1116). Several times forced to fight against Babylonia, the latter was even able to defend himself against an attack by Nebuchadrezzar I.

According to the inscriptions, most of his building efforts were in Nineveh, rather than in the old capital of Ashur.

His son Tiglath-pileser I (Tukulti-apil-Esharra; *c.* 1115–*c.* 1077) raised the power of Assyria to new heights. First he turned against a large army of the Mushki that had entered into southern Armenia from Anatolia, defeating them decisively. After this, he forced the small Hurrian states of southern Armenia to pay him tribute. Trained in mountain warfare themselves and helped by capable pioneers, the Assyrians were now able to advance far into the mountain regions. Their main enemies were the Aramaeans, the Semitic Bedouin nomads whose many small states often combined against the Assyrians. Tiglath-pileser I also went to Syria and even reached the Mediterranean, where he took a sea voyage. After 1100 these campaigns led to conflicts with Babylonia. Tiglath-pileser conquered northern Babylonia and plundered Babylon, without decisively defeating Marduk-nadin-ahhe. In his own country the king paid particular attention to agriculture and fruit growing, improved the administrative system, and developed more thorough methods of training scribes.

Three of his sons reigned after Tiglath-pileser, including Ashur-bel-kala (*c.* 1074–*c.* 1057). Like his father, he fought in southern Armenia and against the Aramaeans with Babylonia as his ally. Disintegration of the empire could not be delayed, however. The grandson of Tiglath-pileser, Ashurnasirpal I (*c.* 1050–*c.* 1032), was sickly and unable to do more than defend Assyria proper against his enemies. Fragments of three of his prayers to Ishtar are preserved; among them is a penitential prayer in which he wonders about the cause of so much adversity. Referring to his many good deeds but admitting his guilt at the same time, he asks for forgiveness and health. According to the king, part of his guilt lay in neglecting to teach his subjects the fear of god. After him, little is known for 100 years.

Disintegration of the empire

State and society during the time of Tiglath-pileser were not essentially different from those of the 13th century. Collections of laws, drafts, and edicts of the court exist that go back as far as the 14th century BC. Presumably, most of these remained in effect. One tablet defining the marriage laws shows that the social position of women in Assyria was lower than in Babylonia or Israel or among the Hittites. A man was allowed to send away his wife at his own pleasure with or without divorce money. In the case of adultery, he was permitted to kill or maim her. Outside her house the woman was forced to observe many restrictions, such as the wearing of a veil. It is not clear whether these regulations carried the weight of law, but they seem to have represented a reaction against practices that were more favourable to women. Two somewhat older marriage contracts, for example, granted equal rights to both partners, even in divorce. The women of the king's harem were subject to severe punishment, including beating, maiming, and death, along with those who guarded and looked after them. The penal laws of the time were generally more severe in Assyria than in other countries of the East. The death penalty was not uncommon. In less serious cases the penalty was forced labour after flogging. In certain cases there was trial by ordeal. One tablet treats the subject of landed property rights. Offenses against the established boundary lines called for extremely severe punishment. A creditor was allowed to force his debtor to work for him, but he could not sell him.

The greater part of Assyrian literature was either taken over from Babylonia or written by the Assyrians in the Babylonian dialect, who modeled their works on Babylonian originals. The Assyrian dialect was used in legal documents, court and temple rituals, and collections of recipes—as, for example, in directions for making perfumes. A new art form was the picture tale: a continuing series of pictures carved on square stelae of stone. The pictures, showing war or hunting scenes, begin at the top of the stela and run down around it, with inscriptions under the pictures explaining them. These and the finely cut seals show that the fine arts of Assyria were beginning to surpass those of Babylonia. Architecture and other forms of the monumental arts also began a further development, such as the double temple with its two towers (ziggurat). Colourful enameled tiles were used to decorate the facades.

ASSYRIA AND BABYLONIA FROM C. 1000 TO C. 750 BC

Assyria and Babylonia until Ashurnasirpal II. The most important factor in the history of Mesopotamia in the 10th century was the continuing threat from the Aramaean seminomads. Again and again, the kings of both Babylonia and Assyria were forced to repel their invasions. Even though the Aramaeans were not able to gain a foothold in the main cities, there are evidences of them in many rural areas. Ashur-dan II (934–912) succeeded in suppressing the Aramaeans and the mountain people, in this way stabilizing the Assyrian boundaries. He reintroduced the use of the Assyrian dialect in his written records.

Aramaean invasions

Adad-nirari II (*c.* 911–891) left detailed accounts of his wars and his efforts to improve agriculture. He led six campaigns against Aramaean intruders from northern Arabia. In two campaigns against Babylonia he forced Shamash-mudammiq (*c.* 930–904) to surrender extensive territories. Shamash-mudammiq was murdered, and a treaty with his successor, Nabu-shum-ukin (*c.* 904–888), secured peace for many years. Tukulti-Ninurta II (*c.* 890–884), the son of Adad-nirari II, preferred Nineveh to Ashur. He fought campaigns in southern Armenia. He was portrayed on stelae in blue and yellow enamel in the late Hittite style, showing him under a winged sun—a theme adopted from Egyptian art. His son Ashurnasirpal II (883–859) continued the policy of conquest and expansion. He left a detailed account of his campaigns, which were impressive in their cruelty. Defeated enemies were impaled, flayed, or beheaded in great numbers. Mass deportations, however, were found to serve the interests of the growing empire better than terror. Through the systematic exchange of native populations, conquered regions were denationalized. The result was a submissive, mixed population in which the Aramaean element became the majority. This provided the labour force for the various public works in the metropolitan centres of the Assyrian empire. Ashurnasirpal II rebuilt Kalakh, founded by Shalmaneser I, and made it his capital. Ashur remained the centre of the worship of the god Ashur—in whose name all the wars of conquest were fought. A third capital was Nineveh.

Ashurnasirpal II was the first to use cavalry units to any large extent in addition to infantry and war-chariot troops. He also was the first to employ heavy, mobile battering rams and wall breakers in his sieges. Following after the conquering troops came officials from all branches of the civil service, because the king wanted to lose no time in incorporating the new lands into his empire. The supremacy of Assyria over its neighbouring states owed much to the proficiency of the government service under the leadership of the minister Gabbilani-eresh. The campaigns of Ashurnasirpal II led him mainly to southern Armenia and Mesopotamia. After a series of heavy wars, he incorporated Mesopotamia as far as the Euphrates River. A campaign to Syria encountered little resistance. There was no great war against Babylonia. Ashurnasirpal, like other Assyrian kings, may have been moved by religion not to destroy Babylonia, which had almost the same gods as Assyria. Both empires must have profited from mutual trade and cultural exchange. The Babylonians, under the energetic Nabu-apla-iddina (*c.* 887–855) attacked the Aramaeans in southern Mesopotamia and occupied the valley of the Euphrates River to about the mouth of the Khābūr River.

Ashurnasirpal, so brutal in his wars, was able to inspire architects, structural engineers, and artists and sculptors to heights never before achieved. He built and enlarged temples and palaces in several cities. His most impressive monument was his own palace in Kalakh, covering a space of 269,000 square feet (25,000 square metres). Hundreds of large limestone slabs were used in murals in the state-rooms and living quarters. Most of the scenes were done in relief, but painted murals also have been found. Most of them depict mythological themes and symbolic fertility rites, with the king participating. Brutal war pictures were aimed to discourage enemies. The chief god of Kalakh was Ninurta, god of war and the hunt. The tower of the temple dedicated to Ninurta also served as an astronomical observatory. Kalakh soon became the cultural centre of the empire. Ashurnasirpal claimed to have entertained 69,574 guests at the opening ceremonies of his palace.

Developments in art and architecture under Ashurnasirpal II

Shalmaneser III and Shamshi-Adad V of Assyria. The son and successor of Ashurnasirpal was Shalmaneser III (858–824). His father's equal in both brutality and energy, he was less realistic in his undertakings. His inscriptions, in a peculiar blend of Assyrian and Babylonian, record his considerable achievements but are not always able to conceal his failures. His campaigns were directed mostly against Syria. While he was able to conquer northern Syria and make it a province, in the south he could only weaken the strong state of Damascus and was unable, even after several wars, to eliminate it. In 841 he laid unsuccessful siege to Damascus. Also in 841 King Jehu of Israel was forced to pay tribute. In his invasion of Cilicia, Shalmaneser had only partial success. The same was true of the kingdom of Urartu in Armenia, from which, however, the troops returned with immense quantities of lumber and building stone. The king and, in later years, the general Dayyan-Ashur went several times to western Iran, where they found such states as Mannai in northwestern Iran and, farther away in the southeast, the Persians. They also encountered the Medes during these wars. Horse tribute was collected.

In Babylonia, Marduk-zakir-shumi I ascended the throne about the year 855. His brother Marduk-bel-usati rebelled against him, and in 851 the king was forced to ask Shalmaneser for help. Shalmaneser was only too happy to oblige; when the usurper had been finally eliminated (850), Shalmaneser went to southern Babylonia, which at that time was almost completely dominated by Aramaeans. There he encountered, among others, the Chaldeans, mentioned for the first time in 878 BC, who were to play a leading role in the history of later times; Shalmaneser made them tributaries.

During his long reign he built temples, palaces, and fortifications in Assyria as well as in the other capitals of his provinces. His artists created many statues and stelae. Among the best known is the Black Obelisk, which includes a picture of Jehu of Israel paying tribute. The bronze doors from the town of Imgur-Enlil (Balawat) in Assyria portray the course of his campaigns and other undertakings in rows of pictures, often very lifelike. Hundreds of delicately carved ivories were carried away from Phoenicia, and many of the artists along with them; these later made Kalakh a centre for the art of ivory sculpture.

In the last four years of the reign of Shalmaneser, the crown prince Ashur-da'in-apla led a rebellion. The old king appointed his younger son Shamshi-Adad as the new crown prince. Forced to flee to Babylonia, Shamshi-Adad V (823–811) finally managed to regain the kingship with the help of Marduk-zakir-shumi I under humiliating conditions. As king he campaigned with varying success in southern Armenia and Azerbaijan, later turning against Babylonia. He won several battles against the Babylonian kings Marduk-balassu-iqbi and Baba-aha-iddina (about 818–12) and pushed through to Chaldea. Babylonia remained independent, however.

Shamshi-Adad V

Adad-nirari III and his successors. Shamshi-Adad V died while Adad-nirari III (810–783) was still a minor. His Babylonian mother, Sammu-ramat, took over the regency, governing with great energy until 806. The Greeks, who called her Semiramis, credited her with legendary accomplishments, but historically little is known about her. Adad-nirari later led several campaigns against the Medes and also against Syria and Palestine. In 804 he reached Gaza, but Damascus proved invincible. He also fought in Babylonia, helping to restore order in the north.

Shalmaneser IV (*c.* 783–773) fought against Urartu, then at the height of its power under King Argishti (*c.* 780–755). He successfully defended eastern Mesopotamia against attacks from Armenia. On the other hand, he lost most of Syria after a campaign against Damascus in 773. The reign of Ashur-dan III (772–755) was shadowed by rebellions and by epidemics of plague. Of Ashur-nirari V (754–746) little is known.

In Assyria the feudal structure of society remained largely unchanged. Many of the conquered lands were combined to form large provinces. The governors of these provinces sometimes acquired considerable independence, particularly under the weaker monarchs after Adad-nirari III. Some of them even composed their own inscriptions. The influx of displaced peoples into the cities of Assyria created large metropolitan centres. The spoils of war, together with an expanding trade, favoured the development of a well-to-do commercial class. The dense population of the cities gave rise to social tensions that only the strong kings were able to contain. A number of the former capitals of the conquered lands remained important as capitals of provinces. There was much new building. A standing occupational force was needed in the provinces, and these troops grew steadily in proportion to the total military forces. There are no records on the training of officers or on military logistics. The civil service also expanded, the largest administrative body being the royal court, with thousands of functionaries and craftsmen in the several residential cities.

The cultural decline about the year 1000 was overcome during the reigns of Ashurnasirpal II and Shalmaneser III. The arts in particular experienced a tremendous resurgence. Literary works continued to be written in Assyrian and were seldom of great importance. The literature that had been taken over from Babylonia was further developed with new writings, although one can rarely distinguish between works written in Assyria and works written in Babylonia. In religion, the official cults of Ashur and Ninurta continued, while the religion of the common people went its separate way.

In Babylonia not much was left of the feudal structure; the large landed estates almost everywhere fell prey to the inroads of the Aramaeans, who were at first half nomadic. The leaders of their tribes and clans slowly replaced the former landlords. Agriculture on a large scale was no longer possible except on the outskirts of metropolitan areas. The predominance of the Babylonian schools for scribes may have prevented the emergence of an Aramaean literature. In any case, the Aramaeans seem to have been absorbed into the Babylonian culture. The religious cults in the cities remained essentially the same. The Babylonian empire was slowly reduced to poverty, except perhaps in some of the cities.

Changes in social structure

In 764, after an epidemic, the Erra epic, the myth of Erra (the god of war and pestilence), was written by Kabti-ilani-Marduk. He invented an original plot, which diverged considerably from the old myths; long discourses of the gods involved in the action form the most important part of the epic. There is a passage in the epic claiming that the text was divinely revealed to the poet during a dream.

THE NEO-ASSYRIAN EMPIRE (746–609)

For no other period of Assyrian history is there an abundance of sources comparable to those available for the interval from roughly 745 to 640. Aside from the large number of royal inscriptions, about 2,400 letters, most of them more or less fragmentary, have been published. Usually the senders and recipients of these letters are the king and high government officials. Among them are reports from royal agents about foreign affairs and letters about cultic matters. Treaties, oracles, queries to the sun god about political matters, and prayers of or for kings contain a great deal of additional information. Last but certainly not least are paintings and wall reliefs, which are often very informative.

Tiglath-pileser III and Shalmaneser V. The decline of Assyrian power after 780 was notable; Syria and considerable lands in the north were lost. A military coup deposed King Ashur-nirari V and raised a general to the throne. Under the name of Tiglath-pileser III (746–727), he brought the empire to its greatest expanse. He reduced the size of the provinces in order to break the partial independence of the governors. He also invalidated the tax privileges of cities such as Ashur and Harran in order to distribute the tax load more evenly over the entire realm. Military equipment was improved substantially. In 746 he went to Babylonia to aid Nabu-naṣir (747–734) in his fight against Aramaean tribes. Tiglath-pileser defeated the Aramaeans and then made visits to the large cities of Babylonia. There he tried to secure the support of the priesthood by patronizing their building projects. Babylonia retained its independence.

His next undertaking was to check Urartu. His campaigns in Azerbaijan were designed to drive a wedge between Urartu and the Medes. In 743 he went to Syria, defeating there an army of Urartu. The Syrian city of Arpad, which had formed an alliance with Urartu, did not surrender so easily. It took Tiglath-pileser three years of siege to conquer Arpad, whereupon he massacred the inhabitants and destroyed the city. In 738 a new coalition formed against Assyria under the leadership of Sam'al (modern Zincirli) in northern Syria. It was defeated, and all the princes from Damascus to eastern Anatolia were forced to pay tribute. Another campaign in 735, this time directed against Urartu itself, was only partly successful. In 734 Tiglath-pileser invaded southern Syria and the Philistine territories in Palestine, going as far as the Egyptian border. Damascus and Israel tried to organize resistance against him, seeking to bring Judah into their alliance. Ahaz of Judah, however, asked Tiglath-pileser for help. In 733 Tiglath-pileser devastated Israel and forced it to surrender large territories. In 732 he advanced upon Damascus, first devastating the gardens outside the city and then conquering the capital and killing the king, whom he replaced with a governor. The queen of southern Arabia, Samsil, was now obliged to pay tribute, being permitted in return to use the harbour of the city of Gaza, which was in Assyrian hands.

Wars against Urartu

The death of King Nabonassar of Babylonia caused a chaotic situation to develop there, and the Aramaean Ukin-zer crowned himself king. In 731 Tiglath-pileser fought and beat him and his allies, but he did not capture Ukin-zer until 729. This time he did not appoint a new king for Babylonia but assumed the crown himself under the name Pulu (Pul in the Old Testament). In his old age he abstained from further campaigning, devoting himself to the improvement of his capital, Kalakh. He rebuilt the palace of Shalmaneser III, filled it with treasures from his wars, and decorated the walls with bas-reliefs. The latter were almost all of warlike character, as if designed to intimidate the onlooker with their presentation of gruesome executions. These pictorial narratives on slabs, sometimes painted, have also been found in Syria, at the sites of several provincial capitals of ancient Assyria.

Tiglath-pileser was succeeded by his son Shalmaneser V (726–722), who continued the policy of his father. As king of Babylonia, he called himself Ululai. Almost nothing is known about his enterprises, since his successor destroyed all his inscriptions. The Old Testament relates that he marched against Hoshea of Israel in 724 after Hoshea had rebelled. He was probably assassinated during the long siege of Samaria. His successor maintained that the god Ashur had withdrawn his support of Shalmaneser V for acts of disrespect.

Sargon II (721–705) and Marduk-apal-iddina of Babylonia. It was probably a younger brother of Shalmaneser who ascended the throne of Assyria in 721. Assuming the old name of Sharru-kin (Sargon in the Bible), meaning "Legitimate King," he assured himself of the support of the priesthood and the merchant class by restoring privileges they had lost, particularly the tax exemptions of the great temples. The change of sovereign in Assyria triggered another crisis in Babylonia. An Aramaean prince from the south, Marduk-apal-iddina II (the biblical Merodach-Baladan), seized power in Babylon in 721 and was able to retain it until 710 with the help of Humbanigash I of Elam. A first attempt by Sargon to recover Babylonia miscarried when Elam defeated him in 721. During the same year the protracted siege of Samaria was brought to a close. The Samarian upper class was deported, and Israel became an

Assyrian province. Samaria was repopulated with Syrians and Babylonians. Judah remained independent by paying tribute. In 720 Sargon squelched a rebellion in Syria that had been supported by Egypt. Then he defeated both Hanunu of Gaza and an Egyptian army near the Egyptian border. In 717 and 716 he campaigned in northern Syria, making the hitherto independent state of Carchemish one of his provinces. He also went to Cilicia in an effort to prevent further encroachments of the Phrygians under King Midas (Assyrian: Mitā).

In order to protect his ally, the state of Mannai, in Azerbaijan, Sargon embarked on a campaign in Iran in 719 and incorporated parts of Media as provinces of his empire; however, in 716 another war became necessary. At the same time, he was busy preparing a major attack against Urartu. Under the leadership of the crown prince Sennacherib, armies of agents infiltrated Urartu, which was also threatened from the north by the Cimmerians. Many of their messages and reports have been preserved. The longest inscription ever composed by the Assyrians about a year's enterprise (430 very long lines) is dedicated to this Urartu campaign of 714. Phrased in the style of a first report to the god Ashur, it is interspersed with stirring descriptions of natural scenery. The strong points of Urartu must have been well fortified. Sargon tried to avoid them by going through the province of Mannai and attacking the Median principalities on the eastern side of Lake Urmia. In the meantime, hoping to surprise the Assyrian troops, Rusa of Urartu had closed the narrow pass lying between Lake Urmia and Sahand Mount. Sargon, anticipating this, led a small band of cavalry in a surprise charge that developed into a great victory for the Assyrians. Rusa fled and died. The Assyrians pushed forward, destroying all the cities, fortifications, and even irrigation works of Urartu. They did not conquer Tushpa (the capital) but took possession of the mountain city of Muṣaṣir. The spoils were immense. The following years saw only small campaigns in Media and eastern Anatolia and against Ashdod, in Palestine. King Midas of Phrygia and some cities on Cyprus were quite ready to pay tribute.

Sargon was now free to settle accounts with Marduk-apal-iddina of Babylonia. Abandoned by his ally Shutruk-Nahhunte II of Elam, Marduk-apal-iddina found it best to flee, first to his native land on the Persian Gulf and later to Elam. Because the Aramaean prince had made himself very unpopular with his subjects, Sargon was hailed as the liberator of Babylonia. He complied with the wishes of the priesthood and at the same time put down the Aramaean nobility. He was satisfied with the modest title of governor of Babylonia.

Sargon's palace

At first Sargon resided in Kalakh, but he then decided to found an entirely new capital north of Nineveh. He called the city Dur-Sharrukin—"Sargonsburg" (modern Khorsabad, Iraq). He erected his palace on a high terrace in the northeastern part of the city. The temples of the main gods, smaller in size, were built within the palatial rectangle, which was surrounded by a special wall. This arrangement enabled Sargon to supervise the priests better than had been possible in the old, large temple complexes. One consequence of this design was that the figure of the king pushed the gods somewhat into the background, thereby gaining in importance. Desiring that his palace match the vastness of his empire, Sargon planned it in monumental dimensions. Stone reliefs of two winged bulls with human heads flanked the entrance; they were much larger than anything comparable built before. The walls were decorated with long rows of bas-reliefs showing scenes of war and festive processions. A comparison with a well-executed stela of the Babylonian king Marduk-apal-iddina shows that the fine arts of Assyria had far surpassed those of Babylonia. Sargon never completed his capital, though from 713 to 705 BC tens of thousands of labourers and hundreds of artisans worked on the great city. Yet, with the exception of some magnificent buildings for public officials, only a few durable edifices were completed in the residential section. In 705, in a campaign in northwestern Iran, Sargon was ambushed and killed. His corpse remained unburied, to be devoured by birds of prey. Sargon's son Sennacherib, who had quarreled with his father, was inclined to believe with the priests that his death was a punishment from the neglected gods of the ancient capitals.

Sennacherib. Sennacherib (Assyrian: Sin-ahhe-eriba; 704–681) was well prepared for his position as sovereign. With him Assyria acquired an exceptionally clever and gifted, though often extravagant, ruler. His father, interestingly enough, is not mentioned in any of his many inscriptions. He left the new city of Dur-Sharrukin at once and resided in Ashur for a few years, until in 701 he made Nineveh his capital.

Sennacherib had considerable difficulties with Babylonia. In 703 Marduk-apal-iddina again crowned himself king with the aid of Elam, proceeding at once to ally himself with other enemies of Assyria. After nine months he was forced to withdraw when Sennacherib defeated a coalition army consisting of Babylonians, Aramaeans, and Elamites. The new puppet king of Babylonia was Bel-ibni (702–700), who had been raised in Assyria.

In 702 Sennacherib launched a raid into western Iran. In 701 there followed his most famous campaign, against Syria and Palestine, with the purpose of gaining control over the main road from Syria to Egypt in preparation for later campaigns against Egypt itself. When Sennacherib's army approached, Sidon immediately expelled its ruler, Luli, who was hostile to Assyria. The other allies either surrendered or were defeated. An Egyptian army was defeated at Eltekeh in Judah. Sennacherib laid siege to Jerusalem, and the king of Judah, Hezekiah, was called upon to surrender, but he did not comply. An Assyrian officer tried to incite the people of Jerusalem against Hezekiah, but his efforts failed. In view of the difficulty of surrounding a mountain stronghold such as Jerusalem, and of the minor importance of this town for the main purpose of the campaign, Sennacherib cut short the attack and left Palestine with his army, which according to the Old Testament (2 Kings 19:35) had been decimated by an epidemic. The number of Assyrian dead is reported to have risen to 185,000. Nevertheless, Hezekiah is reported to have paid tribute to Sennacherib on at least one occasion.

The siege of Jerusalem

Bel-ibni of Babylonia seceded from the union with Assyria in 700. Sennacherib moved quickly, defeating Bel-ibni and replacing him with Sennacherib's oldest son, Ashur-nadin-shumi. The next few years were relatively peaceful. Sennacherib used this time to prepare a decisive attack against Elam, which time and again had supported Babylonian rebellions. The overland route to Elam had been cut off and fortified by the Elamites. Sennacherib had ships built in Syria and at Nineveh. The ships from Syria were moved on rollers from the Euphrates to the Tigris. The fleet sailed downstream and was quite successful in the lagoons of the Persian Gulf and along the southern coastline of Elam. The Elamites launched a counteroffensive by land, occupying Babylonia and putting a man of their choice on the throne. Not until 693 were the Assyrians again able to fight their way through to the north. Finally, in 689, Sennacherib had his revenge. Babylon was conquered and completely destroyed, the temples plundered and leveled. The waters of the Arakhtu Canal were diverted over the ruins, and the inner city remained almost totally uninhabited for eight years. Even many Assyrians were indignant at this, believing that the Babylonian god Marduk must be grievously offended at the destruction of his temple and the carrying off of his image. Marduk was also an Assyrian deity, to whom many Assyrians turned in time of need. A political-theological propaganda campaign was launched to explain to the people that what had taken place was in accord with the wish of most of the gods. A story was written in which Marduk, because of a transgression, was captured and brought before a tribunal. Only a part of the commentary to this botched piece of literature is extant. Even the great poem of the creation of the world, the *Enuma elish,* was altered: the god Marduk was replaced by the god Ashur. Sennacherib's boundless energies brought no gain to his empire, however, and probably weakened it. The tenacity of this king can be seen in his building projects; for example, when Nineveh needed water for irrigation, Sennacherib had his engineers

divert the waters of a tributary of the Great Zab River. The canal had to cross a valley at Jerwan. An aqueduct was constructed, consisting of about two million blocks of limestone, with five huge, pointed archways over the brook in the valley. The bed of the canal on the aqueduct was sealed with cement containing magnesium. Parts of this aqueduct are still standing today. Sennacherib wrote of these and other technological accomplishments in minute detail, with illustrations.

Sennacherib's palace in Nineveh

Sennacherib built a huge palace in Nineveh, adorned with reliefs, some of them depicting the transport of colossal bull statues by water and by land. Many of the rooms were decorated with pictorial narratives in bas-relief telling of war and of building activities. Considerable advances can be noted in artistic execution, particularly in the portrayal of landscapes and animals. Outstanding are the depictions of the battles in the lagoons, the life in the military camps, and the deportations.

In 681 BC there was a rebellion. Sennacherib was assassinated by one or two of his sons in the temple of the god Ninurta at Kalakh. This god, along with the god Marduk, had been badly treated by Sennacherib, and the event was widely regarded as punishment of divine origin.

Esarhaddon. Ignoring the claims of his older brothers, an imperial council appointed Esarhaddon (Ashur-aha-iddina; 680–669) as Sennacherib's successor. The choice is all the more difficult to explain in that Esarhaddon, unlike his father, was friendly toward the Babylonians. It can be assumed that his energetic and designing mother, Zakutu (Naqia), who came from Syria or Judah, used all her influence on his behalf to override the national party of Assyria. The theory that he was a partner in plotting the murder of his father is rather improbable; at any rate, he was able to procure the loyalty of his father's army. His brothers had to flee to Urartu. In his inscriptions, Esarhaddon always mentions both his father and grandfather.

Defining the destruction of Babylon explicitly as punishment by the god Marduk, the new king soon ordered the reconstruction of the city. He referred to himself only as governor of Babylonia and through his policies obtained the support of the cities of Babylonia. At the beginning of his reign the Aramaean tribes were still allied with Elam against him, but Urtaku of Elam (675–664) signed a peace treaty and freed him for campaigning elsewhere. In 679 he stationed a garrison at the Egyptian border, because Egypt, under the Ethiopian king Taharqa, was planning to intervene in Syria. He put down with great severity a rebellion of the combined forces of Sidon, Tyre, and other Syrian cities. The time was ripe to attack Egypt, which was suffering under the rule of the Ethiopians and was by no means a united country. Esarhaddon's first attempt in 674–673 miscarried. In 671 BC, however, his forces took Memphis, the Egyptian capital. Assyrian consultants were assigned to assist the princes of the 22 provinces, their main duty being the collection of tribute.

Occasional threats came from the mountainous border regions of eastern Anatolia and Iran. Pushed forward by the Scythians, the Cimmerians in northern Iran and Transcaucasia tried to gain a foothold in Syria and western Iran. Esarhaddon allied himself with the Scythian king Partatua by giving him one of his daughters in marriage. In so doing he checked the movement of the Cimmerians. Nevertheless, the apprehensions of Esarhaddon can be seen in his many offerings, supplications, and requests to the sun god. These were concerned less with his own enterprises than with the plans of enemies and vassals and the reliability of civil servants. The priestesses of Ishtar had to reassure Esarhaddon constantly by calling out to him, "Do not be afraid." Previous kings, as far as is known, had never needed this kind of encouragement.

Domestic problems

At home Esarhaddon was faced with serious difficulties from factions in the court. His oldest son had died early. The national party suspected his second son, Shamash-shum-ukin, of being too friendly with the Babylonians; he may also have been considered unequal to the task of kingship. His third son, Ashurbanipal, was given the succession in 672, Shamash-shum-ukin remaining crown prince of Babylonia. This arrangement caused much dissension, and some farsighted civil servants warned of disastrous effects. Nevertheless, the Assyrian nobles, priests, and city leaders were sworn to just such an adjustment of the royal line; even the vassal princes had to take very detailed oaths of allegiance to Ashurbanipal, with many curses against perjurers.

Another matter of deep concern for Esarhaddon was his failing health. He regarded eclipses of the moon as particularly alarming omens, and, in order to prevent a fatal illness from striking him at these times, he had substitute kings chosen who ruled during the three eclipses that occurred during his 12-year reign. The replacement kings died or were put to death after their brief term of office. During his off-terms Esarhaddon called himself "Mister Peasant." This practice implied that the gods could not distinguish between the real king and a false one—quite contrary to the usual assumptions of the religion.

Esarhaddon enlarged and improved the temples in both Assyria and Babylonia. He also constructed a palace in Kalakh, using many of the picture slabs of Tiglath-pileser III. The works that remain are not on the level of those of either his predecessors or of Ashurbanipal. He died while on an expedition to put down a revolt in Egypt.

Ashurbanipal (668–627) and Shamash-shum-ukin (668–648). Although the death of his father occurred far from home, Ashurbanipal assumed the kingship as planned. He may have owed his fortunes to the intercession of his grandmother Zakutu, who had recognized his superior capacities. He tells of his diversified education by the priests and his training in armour-making as well as in other military arts. He may have been the only king in Assyria with a scholarly background. As crown prince he also had studied the administration of the vast empire. The record notes that the gods granted him a record harvest during the first year of his reign. There were also good crops in subsequent years. During these first years he also was successful in foreign policy, and his relationship with his brother in Babylonia was good.

In 668 he put down a rebellion in Egypt and drove out King Taharqa, but in 664 the nephew of Taharqa, Tanutamon, gathered forces for a new rebellion. Ashurbanipal went to Egypt, pursuing the Ethiopian prince far into the south. His decisive victory moved Tyre and other parts of the empire to resume regular payments of tribute. Ashurbanipal installed Psamtik (Greek: Psammetichos) as prince over the Egyptian region of Sais. In 656 Psamtik dislodged the Assyrian garrisons with the aid of Carian and Ionian mercenaries, making Egypt again independent. Ashurbanipal did not attempt to reconquer it. A former ally of Assyria, Gyges of Lydia, had aided Psamtik in his rebellion. In return, Assyria did not help Gyges when he was attacked by the Cimmerians. Gyges lost his throne and his life. His son Ardys decided that the payment of tribute to Assyria was a lesser evil than conquest by the Cimmerians.

War with Elam

Graver difficulties loomed in southern Babylonia, which was attacked by Elam in 664. Another attack came in 653, whereupon Ashurbanipal sent a large army that decisively defeated the Elamites. Their king was killed, and some of the Elamite states were encouraged to secede. Elam was no longer strong enough to assume an active part on the international scene. This victory had serious consequences for Babylonia. Shamash-shum-ukin had grown weary of being patronized by his domineering brother. He formed a secret alliance in 656 with the Iranians, Elamites, Aramaeans, Arabs, and Egyptians, directed against Ashurbanipal. The withdrawal of defeated Elam from this alliance was probably the reason for a premature attack by Shamash-shum-ukin at the end of the year 652, without waiting for the promised assistance from Egypt. Ashurbanipal, taken by surprise, soon pulled his troops together. The Babylonian army was defeated, and Shamash-shum-ukin was surrounded in his fortified city of Babylon. His allies were not able to hold their own against the Assyrians. Reinforcements of Arabian camel troops also were defeated. The city of Babylon was under siege for three years. It fell in 648 amid scenes of horrible carnage, Shamash-shum-ukin dying in his burning palace.

After 648 the Assyrians made a few punitive attacks on the Arabs, breaking the forward thrust of the Arab tribes

for a long time to come. The main objective of the Assyrians, however, was a final settlement of their relations with Elam. The refusal of Elam in 647 to extradite an Aramaean prince was used as pretext for a new attack that drove deep into its territory. The assault on the solidly fortified capital of Susa followed, probably in 646. The Assyrians destroyed the city, including its temples and palaces. Vast spoils were taken. As usual, the upper classes of the land were exiled to Assyria and other parts of the empire, and Elam became an Assyrian province. Assyria had now extended its domain to southwestern Iran. Cyrus I of Persia sent tribute and hostages to Nineveh, hoping perhaps to secure protection for his borders with Media. Little is known about the last years of Ashurbanipal's reign.

Ashurbanipal left more inscriptions than any of his predecessors. His campaigns were not always recorded in chronological order but clustered in groups according to their purpose. The accounts were highly subjective. One of his most remarkable accomplishments was the founding of the great palace library in Nineveh (modern Kuyunjik), which is today one of the most important sources for the study of ancient Mesopotamia. The king himself supervised its construction. Important works were kept in more than one copy, some intended for the king's personal use. The work of arranging and cataloging drew upon the experience of centuries in the management of collections in huge temple archives such as the one in Ashur. In his inscriptions Ashurbanipal tells of becoming an enthusiastic hunter of big game, acquiring a taste for it during a fight with marauding lions. In his palace at Nineveh the long rows of hunting scenes show what a masterful artist can accomplish in bas-relief; with these reliefs Assyrian art reached its peak. In the series depicting his wars, particularly the wars fought in Elam, the scenes are overloaded with human figures. Those portraying the battles with the Arabian camel troops are magnificent in execution.

The policy of resettlement

One reason for the durability of the Assyrian empire was the practice of deporting large numbers of people from conquered areas and resettling others in their place. This kept many of the conquered nationalities from regaining their power. Equally important was the installation in conquered areas of a highly developed civil service under the leadership of trained officers. The highest ranking civil servant carried the title of *tartān*, a Hurrian word. The *tartān*s also represented the king during his absence. In descending rank were the palace overseer, the main cupbearer, the palace administrator, and the governor of Assyria. The generals often held high official positions, particularly in the provinces. The civil service numbered about 100,000, many of them former inhabitants of subjugated provinces. Prisoners became slaves but were later often freed.

No laws are known for the empire, although documents point to the existence of rules and standards for justice. Those who broke contracts were subject to severe penalties, even in cases of minor importance: the sacrifice of a son or the eating of a pound of wool and drinking of a great deal of water afterward, which led to a painful death. The position of women was inferior, except for the queen and some priestesses.

As yet there are no detailed studies of the economic situation during this period. The landed nobility still played an important role, in conjunction with the merchants in the cities. The large increase in the supply of precious metals—received as tribute or taken as spoils—did not disrupt economic stability in many regions. Stimulated by the patronage of the kings and the great temples, the arts and crafts flourished during this period. The policy of resettling Aramaeans and other conquered peoples in Assyria brought many talented artists and artisans into Assyrian cities, where they introduced new styles and techniques. High-ranking provincial civil servants, who were often very powerful, saw to it that the provincial capitals also benefited from this economic and cultural growth.

Harran became the most important city in the western part of the empire; in the neighbouring settlement of Huzirina (modern Sultantepe, in northern Syria), the remains of an important library have been discovered. Very few Aramaic texts from this period have been found; the climate of Mesopotamia is not conducive to the preservation of the papyrus and parchment on which these texts were written. There is no evidence that a literary tradition existed in any of the other languages spoken within the borders of the Assyrian empire at this time, except in peripheral areas of Syria and Palestine.

Culturally and economically, Babylonia lagged behind Assyria in this period. The wars with Assyria—particularly the catastrophic defeats of 689 and 648—together with many smaller tribal wars disrupted trade and agricultural production. The great Babylonian temples fared best during this period, since they continued to enjoy the patronage of the Assyrian monarchs. Only a few documents from the temples have been preserved, however. There is evidence that the scribal schools continued to operate, and "Sumerian" inscriptions were even composed for Shamash-shum-ukin. In comparison with the Assyrian developments, the pictorial arts were neglected, and Babylonian artists may have found work in Assyria.

During this period people began to use the names of ancestors as a kind of family name; this increase in family consciousness is probably an indication that the number of old families was growing smaller. By this time the process of "Aramaicization" had reached even the oldest cities of Babylonia and Assyria.

Apparently this era was not very fruitful for literature either in Babylonia or in Assyria. In Assyria numerous royal inscriptions, some as long as 1,300 lines, were among the most important texts; some of them were diverse in content and well composed. Most of the hymns and prayers were written in the traditional style. Many oracles, often of unusual content, were proclaimed in the Assyrian dialect, most often by the priestesses of the goddess Ishtar of Arbela. In Assyria as in Babylonia, the beginnings of a real historical literature are observed; most of the authors have remained anonymous up to the present.

Assyrian royal inscriptions

The many gods of the tradition were worshiped in Babylonia and Assyria in large and small temples, as in earlier times. Very detailed rituals regulated the sacrifices, and the interpretations of the ritual performances in the cultic commentaries were rather different and sometimes very strange.

On some of the temple towers (ziggurats), astronomical observatories were installed. The earliest of these may have been the observatory of the Ninurta temple at Kalakh in Assyria, which dates back to the 9th century BC; it was destroyed with the city in 612. The most important observatory in Babylonia from about 580 was situated on the ziggurat Etemenanki, a temple of Marduk in Babylon. In Assyria the observation of the Sun, Moon, and stars had already reached a rather high level; the periodic recurrence of eclipses was established. After 600, astronomical observation and calculations developed steadily, and they reached their high point after 500, when Babylonian and Greek astronomers began their fruitful collaboration. Incomplete astronomical diaries, beginning in 652 and covering some 600 years, have been preserved.

Decline of the Assyrian empire. Few historical sources remain for the last 30 years of the Assyrian empire. There are no extant inscriptions of Ashurbanipal after 640 BC, and the few surviving inscriptions of his successors contain only vague allusions to political matters. In Babylonia the silence is almost total until 625 BC, when the chronicles resume. The rapid downfall of the Assyrian empire was formerly attributed to military defeat, although it was never clear how the Medes and the Babylonians alone could have accomplished this. More recent work has established that after 635 a civil war occurred, weakening the empire so that it could no longer stand up against a foreign enemy. Ashurbanipal had twin sons. Ashur-etel-ilani was appointed successor to the throne, but his twin brother Sin-shar-ishkun did not recognize him. The fight between them and their supporters forced the old king to withdraw to Harran, in 632 at the latest, perhaps ruling from there over the western part of the empire until his death in 627. Ashur-etel-ilani governed in Assyria from about 633, but a general, Sin-shum-lisher, soon rebelled against him and proclaimed himself counter-king. Some

Internal struggles in the last years of the empire

years later (629?) Sin-shar-ishkun finally succeeded in obtaining the kingship. In Babylonian documents dates can be found for all three kings. To add to the confusion, until 626 there are also dates of Ashurbanipal and a king named Kandalanu. In 626 the Chaldean Nabopolassar (Nabu-apal-uṣur) revolted from Uruk and occupied Babylon. There were several changes in government. King Ashur-etel-ilani was forced to withdraw to the west, where he died sometime after 625.

About the year 626 the Scythians laid waste to Syria and Palestine. In 625 the Medes became united under Cyaxares and began to conquer the Iranian provinces of Assyria. One chronicle relates of wars between Sin-shar-ishkun and Nabopolassar in Babylonia in 625–623. It was not long until the Assyrians were driven out of Babylonia. In 616 the Medes struck against Nineveh, but, according to the Greek historian Herodotus, were driven back by the Scythians. In 615, however, the Medes conquered Arrapkha (Kirkūk), and in 614 they took the old capital of Ashur, looting and destroying the city. Now Cyaxares and Nabopolassar made an alliance for the purpose of dividing Assyria. In 612 Kalakh and Nineveh succumbed to the superior strength of the allies. The revenge taken on the Assyrians was terrible: 200 years later Xenophon found the country still sparsely populated.

Assyrians driven from Babylonia

Sin-shar-ishkun, king of Assyria, found death in his burning palace. The commander of the Assyrian army in the west crowned himself king in the city of Harran, assuming the name of the founder of the empire, Ashur-uballiṭ II (611–609 BC). Ashur-uballiṭ had to face both the Babylonians and the Medes. They conquered Harran in 610, without, however, destroying the city completely. In 609 the remaining Assyrian troops had to capitulate. With this event Assyria disappeared from history. The great empires that succeeded it learned a great deal from the hated Assyrians, both in the arts and in the organization of their states.

THE NEO-BABYLONIAN EMPIRE

The Chaldeans, who inhabited the coastal area near the Persian Gulf, had never been entirely pacified by the Assyrians. About 630 Nabopolassar became king of the Chaldeans. In 626 he forced the Assyrians out of Uruk and crowned himself king of Babylonia. He took part in the wars aimed at the destruction of Assyria. At the same time, he began to restore the dilapidated network of canals in the cities of Babylonia, particularly those in Babylon itself. He fought against the Assyrian Ashur-uballiṭ II and then against Egypt, his successes alternating with misfortunes. In 605 Nabopolassar died in Babylon.

Nebuchadrezzar II. Nabopolassar had named his oldest son, Nabu-kudurri-uṣur, after the famous king of the second dynasty of Isin, trained him carefully for his prospective kingship, and shared responsibility with him. When the father died in 605, Nebuchadrezzar was with his army in Syria; he had just crushed the Egyptians near Carchemish in a cruel, bloody battle and pursued them into the south. On receiving the news of his father's death, Nebuchadrezzar returned immediately to Babylon. In his numerous building inscriptions he tells but rarely of his many wars; most of them end with prayers. The Babylonian chronicle is extant only for the years 605–594, and not much is known from other sources about the later years of this famous king. He went very often to Syria and Palestine, at first to drive out the Egyptians. In 604 he took the Philistine city of Ashkelon. In 601 he tried to push forward into Egypt but was forced to pull back after a bloody, undecided battle and to regroup his army in Babylonia. After smaller incursions against the Arabs of Syria, he attacked Palestine at the end of 598. King Jehoiakim of Judah had rebelled, counting on help from Egypt. According to the chronicle, Jerusalem was taken on March 16, 597. Jehoiakim had died during the siege, and his son, King Johoiachin, together with at least 3,000 Jews, was led into exile in Babylonia. They were treated well there, according to the documents. Zedekiah was appointed the new king. In 596, when danger threatened from the east, Nebuchadrezzar marched to the Tigris River and induced the enemy to withdraw. After a revolt in Babylonia had been crushed with much bloodshed, there were other campaigns in the west.

Campaigns in Syria and Palestine

According to the Old Testament, Judah rebelled again in 589, and Jerusalem was placed under siege. The city fell in 587/586 and was completely destroyed. Many thousands of Jews were forced into "Babylonian exile," and their country was reduced to a province of the Babylonian empire. The revolt had been caused by an Egyptian invasion that pushed as far as Sidon. Nebuchadrezzar laid siege to Tyre for 13 years without taking the city, because there was no fleet at his disposal. In 568/567 he attacked Egypt, again without much success, but from that time on the Egyptians refrained from further attacks on Palestine. Nebuchadrezzar lived at peace with Media throughout his reign and acted as a mediator after the Median-Lydian war of 590–585.

Jerusalem destroyed

The Babylonian empire under Nebuchadrezzar extended to the Egyptian border. It had a well-functioning administrative system. Though he had to collect extremely high taxes and tributes in order to maintain his armies and carry out his building projects, Nebuchadrezzar made Babylonia one of the richest lands in western Asia—the more astonishing because it had been rather poor when it was ruled by the Assyrians. Babylon was the largest city of the "civilized world." Nebuchadrezzar maintained the existing canal systems and built many supplementary canals, making the land even more fertile. Trade and commerce flourished during his reign.

Nebuchadrezzar's building activities surpassed those of most of the Assyrian kings. He fortified the old double walls of Babylon, adding another triple wall outside the old wall. In addition, he erected another wall, the Median Wall, north of the city between the Euphrates and the Tigris rivers. According to Greek estimates, the Median Wall may have been about 100 feet high. He enlarged the old palace and added many wings, so that hundreds of rooms with large inner courts were now at the disposal of the central offices of the empire. Colourful glazed-tile bas-reliefs decorated the walls. Terrace gardens, called the Hanging Gardens in later accounts, were added. Hundreds of thousands of workers must have been required for these projects. The temples were objects of special concern. He devoted himself first and foremost to the completion of Etemenanki, the "Tower of Babel." Construction of this building began in the time of Nebuchadrezzar I, about 1110. It stood as a "building ruin" until the reign of Esarhaddon of Assyria, who resumed building about 680 but did not finish. Nebuchadrezzar II was able to complete the whole building. The mean dimensions of Etemenanki are to be found in the Esagila Tablet, which has been known since the late 19th century. Its base measured about 300 feet on each side, and it was 300 feet in height. There were five terracelike gradations surmounted by a temple, the whole tower being about twice the height of those of other temples. The wide street used for processions led along the eastern side by the inner city walls and crossed at the enormous Ishtar Gate with its world-renowned bas-relief tiles. Nebuchadrezzar also built many smaller temples throughout the country.

The Tower of Babel

The last kings of Babylonia. Awil-Marduk (called Evil-Merodach in the Old Testament; 561–560), the son of Nebuchadrezzar, was unable to win the support of the priests of Marduk. His reign did not last long, and he was soon eliminated. His brother-in-law and successor, Nergal-shar-uṣur (called Neriglissar in classical sources; 559–556), was a general who undertook a campaign in 557 into the "rough" Cilician land, which may have been under the control of the Medes. His land forces were assisted by a fleet. His still-minor son Labashi-Marduk was murdered not long after that, allegedly because he was not suitable for his job.

The next king was the Aramaean Nabonidus (Nabu-na'id; 556–539) from Harran, one of the most interesting and enigmatic figures of ancient times. His mother, Addagoppe, was a priestess of the god Sin in Harran; she came to Babylon and managed to secure responsible offices for her son at court. The god of the moon rewarded her piety with a long life—she lived to be 103—and she was buried in Harran with all the honours of

a queen in 547. It is not clear which powerful faction in Babylon supported the kingship of Nabonidus; it may have been one opposing the priests of Marduk, who had become extremely powerful. Nabonidus raided Cilicia in 555 and secured the surrender of Harran, which had been ruled by the Medes. He concluded a treaty of defense with Astyages of Media against the Persians, who had become a growing threat since 559 under their king Cyrus II. He also devoted himself to the renovation of many temples, taking an especially keen interest in old inscriptions. He gave preference to his god Sin and had powerful enemies in the priesthood of the Marduk temple. Modern excavators have found fragments of propaganda poems written against Nabonidus and also in support of him. Both traditions continued in Judaism.

Internal difficulties and the recognition that the narrow strip of land from the Persian Gulf to Syria could not be defended against a major attack from the east induced Nabonidus to leave Babylonia around 552 and to reside in Taima (Taymā') in northern Arabia. There he organized an Arabian province with the assistance of Jewish mercenaries. His viceroy in Babylonia was his son Bel-shar-uṣur, the Belshazzar of the Book of Daniel in the Bible. Cyrus turned this to his own advantage by annexing Media in 550. Nabonidus, in turn, allied himself with Croesus of Lydia in order to fight Cyrus. Yet, when Cyrus attacked Lydia and annexed it in 546, Nabonidus was not able to help Croesus. Cyrus bode his time. In 542 Nabonidus returned to Babylonia, where his son had been able to maintain good order in external matters but had not overcome a growing internal opposition to his father. Consequently, Nabonidus' career after his return was short-lived, though he tried hard to regain the support of the Babylonians. He appointed his daughter to be high priestess of the god Sin in Ur, thus returning to the Sumerian-Old Babylonian religious tradition. The priests of Marduk looked to Cyrus, hoping to have better relations with him than with Nabonidus; they promised Cyrus the surrender of Babylon without a fight if he would grant them their privileges in return. In 539 Cyrus attacked northern Babylonia with a large army, defeating Nabonidus, and entered the city of Babylon without a battle. The other cities did not offer any resistance either. Nabonidus surrendered, receiving a small territory in eastern Iran. Tradition has confused him with his great predecessor Nebuchadrezzar II. The Bible refers to him as Nebuchadrezzar in the Book of Daniel.

Babylonia's peaceful submission to Cyrus saved it from the fate of Assyria. It became a territory under the Persian crown but kept its cultural autonomy. Even the racially mixed western part of the Babylonian empire submitted without resistance.

Culture of the Neo-Babylonian empire

By 620 the Babylonians had grown tired of Assyrian rule. They were also weary of internal struggle. They were easily persuaded to submit to the order of the Chaldean kings. The result was a surprisingly rapid social and economic consolidation, helped along by the fact that after the fall of Assyria no external enemy threatened Babylonia for more than 60 years. In the cities the temples were an important part of the economy, having vast benefices at their disposal. The business class regained its strength, not only in the trades and commerce but also in the management of agriculture in the metropolitan areas. Livestock breeding—sheep, goats, beef cattle, and horses—flourished, as did poultry farming. The cultivation of corn, dates, and vegetables grew in importance. Much was done to improve communications, both by water and land, with the western provinces of the empire. The collapse of the Assyrian empire had the consequence that many trade arteries were rerouted through Babylonia. Another result of the collapse was that the city of Babylon became a world centre.

The immense amount of documentary material and correspondence that has survived has not yet been fully analyzed. No new system of law or administration seems to have developed during that time. The Babylonian dialect gradually became Aramaicized; it was still written primarily on clay tablets that often bore added material in Aramaic lettering. Parchment and papyrus documents have not survived. In contrast to advances in other fields, there is no evidence of much artistic creativity. Aside from some of the inscriptions of the kings, especially Nabonidus, which were not comparable from a literary standpoint with those of the Assyrians, the main efforts were devoted to the rewriting of old texts. In the fine arts, only a few monuments have any suggestion of new tendencies.

MESOPOTAMIA UNDER THE PERSIANS

Cyrus II, the founder of the Achaemenian Empire, united Babylonia with his country in a personal union, assuming the title of "King of Babylonia, King of the Lands." His son Cambyses was appointed vice-king and resided in Sippar. The Persians relied on the support of the priests and the business class in the cities. In a Babylonian inscription, Cyrus relates with pride his peaceful, bloodless conquest of the city of Babylon. At the same time, he speaks of Marduk as the king of gods. His moderation and restraint were rewarded: Babylonia became the richest province of his empire. There is no indication of any national rebellion in Babylonia under Cyrus and Cambyses (529–522). That there must have been an accumulation of discontent became clear at the ascension to the throne of Darius I (522–486), when a usurper seized the throne of Babylonia under the name of Nebuchadrezzar (III) only to lose both the throne and his life after 10 weeks. Darius waived any punitive action. He had to take more drastic measures in 521, when a new Nebuchadrezzar incited another rebellion. This usurper's reign lasted two months. Executions and plundering followed; Darius ordered that the inner walls of Babylon be demolished, and he reformed the organization of the state. Babylon, however, remained the capital of the new satrapy and also became the administrative headquarters for the satrapies of Assyria and Syria. One result was that the palace had to be enlarged.

Babylonia remained a wealthy and prosperous land, in contrast to Assyria, which was still a poor country. At the same time, the administration of the kingdom was more and more in the hands of the Persians, and the tax burdens grew heavier. This produced discontent, centring especially on the large temples in Babylon. Xerxes (486–465) had his residence in Babylon while he was crown prince, and he knew the country very well. When he assumed his kingship, he immediately curtailed the autonomy of the satrapies. This, in turn, gave rise to many rebellions. In Babylonia there were two short interim governments of Babylonian pretenders during 484–482. Xerxes retaliated by desecrating and partially destroying the holy places of the god Marduk and the Tower of Babel in the city of Babylon. Priests were executed, and the statue of Marduk was melted down.

Xerxes

The members of the royal family still resided in the palaces of the city of Babylon, but Aramaic became more and more the language of the official administration. One source of information for this period are the clay-tablet archives of the commercial house of Murashu and Sons of Nippur for the years of 455–403, which tell much about the important role the Iranians played in the country. The state domains were largely in their hands. They controlled many minor feudal tenants, grouped into social classes according to ancestry and occupation. The business people were predominantly Babylonians and Aramaeans, but there were also Jews.

The documents become increasingly sparse after 400. The cultural life of Babylon became concentrated in a few central cities, particularly Babylon and Uruk; Ur and Nippur were also important centres. The work of astronomers continued, as evidenced in records of observations. Naburimanni, living and working around 500, and Kidinnu, 5th or 4th century BC, were known to the Greeks; both astronomers are famous for their methods of calculating the courses of the Moon and the planets. In the field of literature, religious poetic works as well as texts of omens and Sumero-Akkadian word lists were constantly copied, often with commentaries. (W.T.v.S.)

Mesopotamia from *c.* 320 BC to *c.* AD 620

The political history of Mesopotamia between about 320 BC and AD 620 is divided among three periods of foreign rule—the Seleucids to 141 BC, the Parthians to AD 224,

Mesopotamia in Seleucid-Parthian times.

and the Sāsānians until the Arab invasions of the 7th century AD. Sources are scarce, consisting mainly of a few notices in the works of classical authors such as Strabo, Pliny, Polybius, and Ptolemy, while the cuneiform sources are mainly incantations, accounts of religious rites, and copies of ancient religious texts.

THE SELEUCID PERIOD

At the end of the Achaemenian Empire, Mesopotamia was partitioned into the satrapy of Babylonia in the south, while the northern part of Mesopotamia was joined with Syria in another satrapy. It is not known how long this division lasted, but, by the death of Alexander the Great in 323 BC, the north was removed from Syria and made a separate satrapy.

Seleucus

In the wars between the successors of Alexander, Mesopotamia suffered much from the passage and the pillaging of armies. When Alexander's empire was divided in 321 BC, one of his generals, Seleucus (later Seleucus I Nicator), received the satrapy of Babylonia to rule. From about 315 to about 312 BC, however, Antigonus I Monophthalmus (The "One-Eyed") took over the satrapy as ruler of all Mesopotamia, and Seleucus had to flee and accept refuge with Ptolemy of Egypt. With the aid of Ptolemy, Seleucus was able to enter Babylon in 312 BC (311 by the Babylonian reckoning) and hold it for a short time against the forces of Antigonus before marching to the east, where he consolidated his power. It is uncertain when he returned to Babylonia and reestablished his rule there; it may have been in 308, but by 305 BC he had assumed the title of king. With the defeat and death of Antigonus at the Battle of Ipsus in 301, Seleucus became the ruler of a large empire stretching from modern Afghanistan to the Mediterranean Sea. He founded a number of cities, the most important of which were Seleucia, on the Tigris, and Antioch, on the Orontes River in Syria. The latter, named after his father or his son, both of whom were called Antiochus, became the principal capital, while Seleucia became the capital of the eastern provinces. The dates of the founding of these two cities are unknown, but presumably Seleucus founded Seleucia after he became king, while Antioch was built after the defeat of Antigonus.

Mesopotamia is scarcely mentioned in the Greek sources relating to the Seleucids, because the Seleucid rulers were occupied with Greece and Anatolia and with wars with the Ptolemies of Egypt in Palestine and Syria. Even the political division of Mesopotamia is uncertain, especially since Alexander, Seleucus, and Seleucus' son Antiochus I Soter all founded cities that were autonomous, like the Greek polis. The political division of the land into 19 or 20 small satrapies, which is found later, under the Parthians, began under the Seleucids. Geographically, however, Mesopotamia can be divided into four areas: Characene, also called Mesene, in the south; Babylonia, later called Asūristān, in the middle; northern Mesopotamia, where there was later a series of small states such as Gordyene, Osroene, Adiabene, and Garamea; and finally the desert areas of the upper Euphrates, in Sāsānian times called Arabistān. These four areas had different histories down to the Arab conquest in the 7th century, although all of them were subject first to the Seleucids and then to the Parthians and Sāsānians. At times, however, several of the areas were fully independent, in theory as well as in fact, while the relations of certain cities with provincial governments and with the central government varied. From cuneiform sources it is known that traditional religious practices and forms of government as well as other customs continued in Mesopotamia; there were only a few Greek centres, such as Seleucia and the island of Ikaros (modern Faylakah, near Kuwait), where the practices of the Greek polis held sway. Otherwise, native cities had a few Greek officials or garrisons but continued to function as they had in the past.

Geographic divisions

Seleucia on the Tigris was not only the eastern capital but also an autonomous city ruled by an elected senate, and it replaced Babylon as the administrative and commercial centre of the old province of Babylonia. In the south several cities, such as Furat and Charax, grew rich

on the maritime trade with India; Charax became the main entrepôt for trade after the fall of the Seleucids. In the north there was no principal city, but several towns, such as Arbela (modern Irbīl) and Nisibis (modern Nusaybin), later became important centres. In the desert region, "caravan cities" such as Hatra and Palmyra began their rise in the Seleucid period and had their heyday under the Parthians.

The only time that the Seleucid kings lost control of Mesopotamia was from 222 to 220 BC, when Molon, the governor of Media, revolted and marched to the west. When the new Seleucid king, Antiochus III, moved against him from Syria, however, Molon's forces deserted him, and the revolt ended. The Parthians, under their able king Mithradates I, conquered Seleucid territory in Iran and entered Seleucia in 141 BC. After the death of Mithradates I in 138 BC, Antiochus VII began a campaign to recover the Seleucid domains in the east. This campaign was successful until Antiochus VII lost his life in Iran in 129 BC. His death ended Seleucid rule in Mesopotamia and marked the beginning of small principalities in both the south and north of Mesopotamia.

Seleucid rule brought changes to Mesopotamia, especially in the cities where Greeks and Macedonians were settled. In these cities the king usually made separate agreements with the Greek officials of the city regarding civil and military authority, immunity from taxes or corvée, or the like. Native cities continued with their old systems of local government, much as they had under the Achaemenians. Greek gods were worshiped in temples dedicated to them in the Greek cities, and native Mesopotamian gods had temples dedicated to them in the native cities. In time, however, syncretism and identification of the foreign and local deities developed. Although the policy of Hellenization was not enforced upon the population, Greek ideas did influence the local educated classes, just as local practices were gradually adopted by the Greeks. As in Greece and the lands of the eastern Mediterranean, in Mesopotamia the philosophies of the Stoics and other schools probably had an impact, as did mystery religions; both were hallmarks of the Hellenistic Age. Unfortunately there is no evidence from the east on the popularity of Greek beliefs among the local population, and scholars can only speculate on the basis of the fragmentary notices in authors such as Strabo. The Seleucid rulers respected the native priesthoods of Mesopotamia, and there is no record of any persecutions. On the contrary, the rulers seem to have favoured local religious practices, and ancient forms of worship continued. Cuneiform writing by priests, who copied incantations and old religious texts, continued into the Parthian period.

The influence of Greek philosophy and religion

The administrative institutions of the countryside of Mesopotamia remained even more traditional than those of the cities; the old taxes were simply paid to new masters. The satrapy, much reduced in size from Achaemenian times, was the basis for Seleucid control of the countryside. A satrap or strategus (a military title) headed each satrapy, and the satrapies were divided into hyparchies or eparchies; the sources that use these and other words, such as toparchy, are unclear about the subdivisions of the satrapy. There was a great variety of smaller units of administration. In the capital and in the provincial centres, both Greek and Aramaic were used as the written languages of the government. The use of cuneiform in government documents ceased sometime during the Achaemenian period, but it continued in religious texts until the 1st century of the Common era. The archives were managed both in the capital and in provincial cities by an official called a *bibliophylax*. There were many financial officials (*oikonomoi*); some of them oversaw royal possessions, and others managed local taxes and other economic matters. The legal system in the Seleucid empire is not well understood, but presumably both local Mesopotamian laws and Greek laws, which had absorbed or replaced old Achaemenian imperial laws, were in force. Excavations at Seleucia have uncovered thousands of seal impressions on clay, evidence of a developed system of controls and taxes on commodities of trade. Many of the sealings are records of payment of a salt tax. Most of the tolls and tariffs, however, were local assessments rather than royal taxes.

Artistic remains from the Seleucid period are exceedingly scarce, and, in contrast to Achaemenian art, no royal or monumental art has been recovered. One might characterize the objects that can be dated to the Seleucid era as popular or private art, such as seals, statuettes, and clay figurines. Both Greek and local styles are found, with an amalgam of styles prevalent at the end of Seleucid rule, evidence of a syncretism in cultures. The numerous statues and statuettes of Heracles found in the east testify to the great popularity of the Greek deity, in Mesopotamia identified with the local god Nergal.

Aramaic was the "official" written langauge of the Achaemenian Empire; after the conquests of Alexander the Great, Greek, the language of the conquerors, replaced Aramaic. Under the Seleucids, however, both Greek and Aramaic were used throughout the empire, although Greek was the principal language of government. Gradually Aramaic underwent changes in different parts of the empire, and in Mesopotamia in the time of the Parthians it evolved into Syriac, with dialectical differences from western Syriac, used in Syria and Palestine. In southern Mesopotamia, other dialects evolved, one of which was Mandaic, the scriptural language of the Mandaean religion.

Literature

Literature in local languages is nonexistent, except for copies of ancient religious texts in cuneiform writing and fragments of Aramaic writing. There were authors who wrote in Greek, but little of their work has survived and that only as excerpts in later works. The most important of these authors was Berosus, a Babylonian priest who wrote about the history of his country, probably under Antiochus I (reigned 281–261 BC). Although the excerpts of his work that are preserved deal with the ancient, mythological past and with astrology and astronomy, the fact that they are in Greek is indicative of interest among local Greek colonists in the culture of their neighbours. Another popular author was Apollodorus of Artemita (a town near Seleucia), who wrote under the Parthians a history of Parthia in Greek as well as other works on geography. Greek continued to be a lingua franca used by educated people in Mesopotamia well into the Parthian period.

Under the Seleucid system of dating, as far as is known, a fixed year became the basis for continuous dating for the first time in the Middle East. The year chosen was the year of entry of Seleucus into Babylon, 311 BC according to the Mesopotamian reckoning and 312 BC according to the Syrians. Before this time, dating had been only according to the regnal years of the ruling monarch (*e.g.*, "fourth year of Darius"). The Parthians, following the Seleucids, sought to institute their own system of reckoning based on some event in their past that scholars can only surmise—possibly the assumption of the title of king by the first ruler of the Parthians, Arsaces.

Since Greece was overpopulated at the beginning of Seleucid rule, it was not difficult to persuade colonists to come to the east, especially when they were given plots of land (*clerοii*) from royal domains that they could pass on to their descendants; if they had no descendants, the land would revert to the king. Theoretically all land belonged to the ruler, but actually local interests prevailed. As time passed, however, the influx of Greek colonists diminished and then ended when the wars of the Hellenistic kings interrupted this movement. Nonetheless, Greek influences continued, and it is fascinating to find in cuneiform documents records of families where the father has a local name and his son a Greek one, and vice versa. Inasmuch as Mesopotamia was peaceful under the Seleucids, the processes of accommodation and assimilation among the people appear to have flourished.

THE PARTHIAN PERIOD

The coming of the Parthians changed Mesopotamia even less than the establishment of the Seleucid kingdom had, for as early as the middle of the 2nd century BC local dynasts had proclaimed their independence. There is no evidence indicating whether the cities of Mesopotamia surrendered piecemeal or all at once or whether they submitted voluntarily or after fighting. In any case, Seleu-

cia was treated better by the Parthians than it had been by the Seleucids, and the local government retained its autonomy. Parthian troops did not occupy Seleucia but remained in a garrison site called Ctesiphon near Seleucia; it later grew into a city and replaced Seleucia as the capital. In Characene in southern Mesopotamia a Seleucid satrap with an Iranian name, Hyspaosines, issued coins about 125 BC, a sign of his independence; the actual date for this may have been earlier. He changed the name of the city Antiochia on the lower Tigris to Spasinou Charax, meaning "The Fort of Hyspaosines," and made it his capital. All the coins issued from his capital have Greek legends. His troops moved north and occupied Babylon and Seleucia probably sometime in 127 BC, when the Parthians were fighting nomadic invaders in the eastern part of their territory. His rule there must have been short, however, for the Parthian governor of Babylon and the north, Himerus, was back in Seleucia and Babylon by 126. Himerus could not have been a rebel, since he struck coins in the name of the Parthian rulers Phraates II and Artabanus II, both of whom were killed in fighting in eastern Iran. Himerus abused his power and is said to have oppressed the cities of Mesopotamia, plundering them and killing their inhabitants. Cuneiform documents from Babylon stop after this date, indicating that the city did not survive the depredations of Himerus. He vanished, however, and Parthian sovereignty was restored by the ninth Arsacid king, Mithradates II, who came to the throne about 124 BC; he was the son of Artabanus II. Mithradates II recovered all Mesopotamia and conquered Characene, overstriking coins of Hyspaosines and driving him from his capital in 122 or 121 BC. By 113, if not earlier, Dura-Europus on the Euphrates was in Parthian hands. In 95 BC the Armenian Tigranes II, a hostage at the court of Mithradates, was placed on the throne of Armenia by his Parthian overlord, and the small kingdoms of northern Mesopotamia—Adiabene, Gordyene, and Osroene—gave allegiance to Mithradates. Mithradates II died about 87 BC, although he may have died earlier, since the period after 90 BC is dark and a usurper named Gotarzes may have ruled for a few years in Mesopotamia. During the reign of Mithradates II the first contacts with Rome, under Lucius Cornelius Sulla, were made, and portents of future struggles were evident in the lack of any agreement between the two powers. Sulla was sent to the east by the Roman Senate to govern Cilicia in Anatolia. In 92 BC Orobazes, an ambassador from Mithradates II, came to him seeking a treaty, but nothing was concluded, since instructions from Rome did not include negotiations with the Parthian power.

Mithradates II

Tigranes II took advantage of struggles between several claimants to the Parthian throne to expand Armenian territory into Mesopotamia, and the small states in the north gave him their allegiance. It was not until 69 BC, when the Roman general Lucius Licinius Lucullus captured Tigranokerta, Tigranes' capital, that Mesopotamia returned to Parthian rule. Thereafter wars between the Romans and the Parthians were to dominate the political history of Mesopotamia.

The Parthians left the local administrations and rulers intact when they conquered Mesopotamia. According to Pliny the Elder (*Natural History* VI. 112) the Parthian empire consisted of 18 kingdoms, 11 of which were called the upper kingdoms (or satrapies), while 7 were called lower kingdoms, meaning that they were located on the plains of Mesopotamia. The centre of the lower kingdoms was ancient Babylonia, called Beth Aramaye in Aramaic, and it was governed directly by the Parthian ruler. In the south was Characene, while to the northeast of Ctesiphon, which had supplanted Seleucia as the Parthian capital, was Garamea, with its capital at modern Kirkūk. Adiabene had Arbela as its capital, and farther north was a province called Beth Nuhadra in Aramaic, which seems to have been governed by a general who was directly responsible to the Parthian king, because this province bore the brunt of Roman invasions. Nisibis was the main city of the desert area of Arabistān, but at the end of the Parthian period the desert caravan city of Hatra claimed hegemony over this area. There were other principalities in the northwest: Sophene, where Tigranes' capital was located; Gordyene and Zabdicene (near modern Çölemerik in eastern Turkey), located to the east of Sophene; and Osroene, with its capital Edessa (modern Urfa, Tur.), which lay inside the Roman sphere of influence. Rule over so many small kingdoms gave Mithradates II the title "King of Kings," also borne by later Parthian rulers.

The defeat of the Roman legions under Marcus Licinius Crassus by the Parthians at the Battle of Carrhae (Carrhae is the Roman name for Harran) in 53 BC heralded a period of Parthian power and expansion in the Middle East, but the tide turned under Mark Antony in 36–34 BC, and thereafter the power structure in the east remained volatile, with the two great states, Rome and Parthia, contending for predominance in the region. Armenia was a perennial bone of contention between the two powers, each of which sought to put its candidate on the throne.

Conflict between Rome and Parthia

Parthian rule was not firm over all Mesopotamia; thus, for example, during the reign of Artabanus III (AD 12–38) the Jewish brigands Asinaeus and Anilaeus set up a free state north of Ctesiphon that lasted 15 years before it was overcome by the Parthians. With the end of cuneiform records and with the attention of classical sources turned to the wars between the Romans and the Parthians, information about internal affairs in Mesopotamia becomes almost nonexistent. Hellenism continued to flourish, for many Parthian kings had the epithet "Philhellene" placed on their coins, but during the last two centuries of Parthian rule Greek influences declined in favour of Iranian ones, while central authority suffered from the usurpations of powerful nobles and local kings. From coinage it is known that the city of Seleucia revolted against central control at the end of Artabanus' reign and maintained its independence for a number of years. Peace was broken by the Roman emperor Nero, who sought to put his client on the throne of Armenia, but, after several years of conflict, peace was arranged in 63. Vologeses I (*c.* AD 51–80) founded the city Vologesias, near Seleucia, as his capital, but the whole area (including Ctesiphon and Seleucia) became an urban complex called Māḥōzē in Aramaic and Al-Madā'in in Arabic; both names mean "The Cities."

Internal rivalries in the Parthian state gave the Romans an opportunity to attack, and control over Armenia was the casus belli for the Roman emperor Trajan's advance into Mesopotamia in 116. Adiabene, as well as the entire Tigris-Euphrates basin of northern Mesopotamia, was incorporated as a province into the Roman Empire. Trajan advanced to the Persian Gulf, but he died of illness and his successor Hadrian made peace, abandoning the conquests in Mesopotamia, although client states remained.

The second century of the Common era was a dark period in Parthian history, but it was a time of growth in wealth and influence of the caravan cities of Palmyra, Hatra, and Mesene (formerly Characene, situated at the confluence of the Tigris and Euphrates). Armenia continued to be a bone of contention between the two great powers, and hostilities occasionally flared up. In 164–165 the Roman general Gaius Avidius Cassius captured the capital cities Ctesiphon and Seleucia, but an epidemic forced the Romans to retreat and peace was restored. Returning soldiers spread the disease throughout the Roman Empire, with devastating consequences. The terms of peace favoured the Romans, who secured control of Nisibis and the Khābūr River valley. The next great war was the invasion of the Roman emperor Septimius Severus to punish the Parthians, who had supported his rival Pescennius Niger and had annexed some territory in Mesopotamia in return for their support. Severus took and sacked Ctesiphon in 198. Because the devastated countryside contained no supplies for the Romans, they were soon compelled to retreat. A siege of Hatra in 199 by Severus failed, and peace was made. Conflict between two claimants to the Parthian throne, Vologeses IV or V and Artabanus V, gave the Roman emperor Caracalla an excuse to invade Adiabene, but in 217 he was assassinated on the road from Edessa to Carrhae, and the Romans made peace. The end of the Parthian kingdom was near, and the advent of the Sāsānians brought a new phase in the history of Mesopotamia.

Parthian rule brought little change in the administration

and institutions of Mesopotamia as it had existed under the Seleucids, except for a general weakening of central authority under the feudal Parthians. The Parthians instituted a new era, beginning in 247 BC, but it paralleled rather than replaced the Seleucid era of reckoning, and the Parthian vanished at the end of the dynasty. As far as can be determined, Hellenism was never proscribed under the Parthians, although it grew weaker toward the end of Parthian rule. From archaeological surveys around Susa, located in the kingdom of Elymais in modern Khūzestān, and from the Diyālā plain northeast of Ctesiphon, it seems that the population of the land increased greatly under the Parthians, as did trade and commerce. The coinage of the later Parthian rulers became more and more debased, probably as a result of the many internecine wars and the lack of control by the central authority. Local rulers also issued their own coinages in Persis, Elymais, Mesene, and elsewhere.

Demographic changes

Changes took place in the demography of Mesopotamia under the Parthians, and perhaps the most striking development among the population was the increase of Arab infiltration from the desert, which resulted in Arab dynasties in the oasis settlements of Palmyra and Hatra. Similarly, an influx of Armenian settlers in the north changed the composition of the local population. After the fall of the Temple of Jerusalem to the Romans in 70, many Jews fled to Mesopotamia, where they joined their coreligionists; Nehardea, north of Ctesiphon, became a centre of Jewish population. Naturally also many migrants from the east came to Mesopotamia in the wake of the Parthian occupation. With many merchants from east and west passing through or remaining in Mesopotamia, the population became more diverse than it had previously been.

During the Parthian occupation the ancient religion and cults of Mesopotamia came to an end and were replaced by mixed Hellenic and Oriental mystery religions and Iranian cults. Local Semitic cults of Bel, Allat, and other deities flourished alongside temples dedicated to Greek gods such as Apollo. The sun deity Shamash was worshiped at Hatra and elsewhere, but the henotheism of the ancient Middle East was giving way to acceptance of universalist religions, if the prevalent view cannot yet be called one of monotheism. In Mesopotamia, in particular, the influence of Jewish monotheism, with the beginning of rabbinic schools and the organization of the community under a leader, the exilarch (*resh galuta* in Aramaic), must have had a significant influence on the local population. Toward the end of the reign of Artabanus III, the royal family of Adiabene converted to Judaism. In the first two centuries of the Common era, Christianity and various baptismal sects also began to expand into Mesopotamia. So far no Mithraeums (underground temples for the worship of the god Mithra), such as existed in the Roman Empire, have been found in Mesopotamia, except at Dura-Europus, where Roman troops were stationed. Many local cults and shrines, such as that of the Sabians and their moon deity at Harran, however, continued to exist until the Islāmic conquest. Parthian Zoroastrianism reinforced local Zoroastrian communities in Mesopotamia left from the time of the Achaemenians, and one of the Gnostic baptismal religions, Mandaeanism, which is still in existence, had its beginning at this time. Although Christian missionaries were active in Mesopotamia in the Parthian period, no centres, such as the one established later at Nisibis, have been reported, and it may be supposed that their activity at first was mainly confined to Jewish communities.

Art and architecture

Archaeological evidence indicates that the Parthians had a more marked influence on art and architecture. Local schools of art flourished, and at first Greek ideals predominated, but in the last two centuries of Parthian rule a "Parthian style" is evident in the art recovered from Mesopotamia and other regions. Whereas Achaemenian and Sāsānian art are royal or imperial and monumental, Parthian art, like Seleucid art, can be characterized as "popular." Parthian works of art reflect the many currents of culture among the populace, and one may say that it is expressionist and stylized, in contrast with Greek and Roman naturalistic or realistic art. The characteristics of Parthian art in Mesopotamia are total frontality (*i.e.*, the representation of figures in full face) in portraits, along with an otherworldly quality. In Middle Eastern art from previous periods, figures were almost always shown in profile. Another new feature of Parthian art is the frequent portrayal of the "flying gallop" in sculpture and painting, not unexpected in view of the importance of cavalry and mounted archers in the Parthian armies. Likewise, Parthian costume, with baggy trousers, became the mode over much of the Middle East and is portrayed in painting and sculpture. In architecture the use of *ayvan*s (arches in porticoes) and domed vaults is attributed to the Parthian period; they may have originated in Mesopotamia. Parthian art influenced that of the Nabataeans in Roman territory, as it did others throughout the Middle East.

Parthian was an Iranian language written in the Aramaic alphabet. It had an enormous number of words and even phrases that were borrowed from Aramaic, and scribal training was necessary to learn these. Syriac, being a Semitic language with emphasis on consonants, evolved several alphabets based on the Aramaic alphabet. The Aramaic alphabet was better suited to Syriac than to Parthian phonology. Parthian was therefore difficult to read and was mainly used by scribes or priests for official or religious writings.

The largest lacuna is in literature from the Parthian period. The largely oral literature of the Parthians, famous for their minstrels and poetry, does not seem to have found many echoes in Mesopotamia, where the settled society contrasted with the heroic, chivalric, and feudal society of the Iranian nomads that continued to dominate Parthian mores even after they had settled in Mesopotamia. Nonetheless, the end of the Parthian period saw the beginning of Syriac literature, which is Christian Aramaic, and some of early Syriac literature, such as the "Song of the Pearl," contains Parthian elements. In the realm of language, rather than literature, the writing of Aramaic changes to Parthian in the 2nd century AD, as can be seen from a bilingual (Greek and Parthian) inscription on a bronze statue from Seleucia dated AD 150–151. It tells how Vologeses III defeated the king of Mesene and took over the entire country. After this period one no longer speaks of Aramaic, but of Parthian and Syriac written in a new cursive alphabet.

THE SĀSĀNIAN PERIOD

The Sāsānian period marks the end of the ancient and the beginning of the medieval era in the history of the Middle East. Universalist religions such as Christianity, Manichaeism, and even Zoroastrianism and Judaism absorbed local religions and cults at the beginning of the 3rd century. Both the Sāsānian and the Roman empires ended by adopting an official state religion, Zoroastrianism for the former and Christianity for the latter. In Mesopotamia, however, older cults such as that of the Mandaeans, the moon cult of Harran, and others continued alongside the great religions. The new rulers were not as tolerant as the Seleucids and Parthians had been, and persecutions occurred under Sāsānian rule.

Ardashīr I

After Ardashīr I, the first of the Sāsānians, consolidated his position in Persis (modern Fārs province), he moved into southern Mesopotamia, and Mesene submitted. In 224 he defeated and killed the last Parthian ruler, Artabanus V, after which Mesopotamia quickly fell before him and Ctesiphon became the main capital of the Sāsānian empire. In 230 Ardashīr besieged Hatra but failed to take it. Hatra called on Roman aid, and in 232 the Roman emperor Severus Alexander launched a campaign that halted Ardashīr's progress. At the death of Severus Alexander in 235 the Sāsānians took the offensive, and probably in 238 Nisibis and Harran came under their control. Hatra was probably captured in early 240, after which Ardashīr's son Shāpūr was made coregent; Ardashīr himself died soon afterward. The Roman emperor Gordian III led a large army against Shāpūr I in 243. The Romans retook Harran and Nisibis and defeated the Sāsānians at a battle near Resaina, but at Anbār, renamed Pērōz-Shāpūr ("Victorious Is Shāpūr"), the Sāsānians inflicted a defeat on the Romans, who lost their emperor. His successor, Philip the Arabian,

made peace, giving up Roman conquests in northern Mesopotamia. Osroene, however, which had been returned to the local ruling family of Abgar by Gordian, remained a vassal state of the Romans. Shāpūr renewed his attacks and took many towns, including Dura-Europus, in 256 and later moved into northern Syria and Anatolia. The defeat and capture of the Roman emperor Valerian at the gates of Edessa, probably in 259, was the high point of his conquests in the west. On Shāpūr's return to Ctesiphon the ruler of Palmyra, Septimius Odaenathus (also called Odainath), attacked and defeated his army, seizing booty. Odeanathus took the title of emperor, conquered Harran and Nisibis, and threatened Ctesiphon in 264–266. His murder relieved the Sāsānians, and in 273 the Roman emperor Aurelian sacked Palmyra and restored Roman authority in northern Mesopotamia. Peace between the two empires lasted until 283, when the Roman emperor Carus invaded Mesopotamia and advanced on Ctesiphon, but the Roman army was forced to withdraw after Carus' sudden death. In 296 Narseh I, the seventh Sāsānian king, took the field and defeated a Roman force near Harran, but in the following year he was defeated and his family was taken captive. As a result, the Romans secured Nisibis and made it their strongest fortress against the Sāsānians. The Roman province of Mesopotamia, which was the land between the Euphrates and Tigris in the northern foothills, became in effect a military area with *limes* (the fortified frontiers of the Roman Empire) and highly fortified towns.

Under Shāpūr II the Sāsānians again took the offensive, and the first war lasted from 337 to 350; it ended with no result as Nisibis was successfully defended by the Romans. In 359 Shāpūr again invaded Roman territory and captured the Roman fortress Amida after a long and costly siege. In 363 the emperor Julian advanced almost to Ctesiphon, where he died, and his successor Jovian had to give up Nisibis and other territories in the north to the Sāsānians. The next war lasted from 502 to 506 and ended with no change. War broke out again in 527, lasting until 531, and even the Byzantine general Belisarius was not able to prevail; as usual, the boundaries remained unchanged. In 540 the Sāsānian king Khosrow (Chosroes) I invaded Syria and even took Antioch, although many fortresses behind him in northern Mesopotamia remained in Byzantine hands. After much back-and-forth fighting, peace was made in 562. War with the Byzantine Empire resumed 10 years later, and it continued under Khosrow's successor, Hormizd IV. Only in 591, in return for their assistance in the restoration to the Sāsānian throne of Khosrow II, who had been deposed and had fled to Byzantine territory, did the Byzantines regain territory in northern Mesopotamia. With the murder in 602 of the Byzantine emperor Maurice, who had been Khosrow's benefactor, and the usurpation of Phocas, Khosrow II saw a golden opportunity to enlarge Sāsānian domains and to take revenge for Maurice. Persian armies took all northern Mesopotamia, Syria, Palestine, Egypt, and Anatolia. By 615, Sāsānian forces were in Chalcedon, opposite Constantinople. The situation changed completely with the new Byzantine emperor Heraclius, who, in a daring expedition into the heart of enemy territory in 623–624, defeated the Sāsānians in Media. In 627–628 he advanced toward Ctesiphon, but, after sacking the royal palaces at Dastagird, northeast of Ctesiphon, he retreated.

Wars with the Byzantine Empire

After the death of Khosrow II, Mesopotamia was devastated not only by the fighting but also by the flooding of the Tigris and Euphrates, by a widespread plague, and by the swift succession of Sāsānian rulers, which caused chaos. Finally in 632 order was restored by the last king, Yazdegerd III, but in the following year the expansion of the Muslim Arabs began and the end of the Sāsānian empire followed a few years afterward.

Unlike the Parthians, the Sāsānians established their own princes as rulers of the small kingdoms they conquered, except on the frontiers, where they accepted vassals or allies because their hold over the frontier regions was insecure. By placing Sāsānian princes over the various parts of the empire, the Sāsānians maintained more control than the Parthians had. The provincial divisions were more systematized, and there was a hierarchy of four units—the satrapy (*shahr* in Middle Persian), under which came the province (*ōstan*), then a district (*tassug*), and finally the village (*deh*). In Mesopotamia these divisions were changed throughout Sāsānian history, frequently because of Roman invasions.

Many native tax collectors were replaced by Persians, who were more trusted by the rulers. In addition to the many tolls and tariffs, corvée, and the like, the two basic taxes were the land and poll taxes. The latter were not paid by the nobility, soldiers, civil servants, and the priests of the Zoroastrian religion. The land tax was a percentage of the harvest, but it was determined before the collection of the crops, which naturally caused many problems. Khosrow I undertook a new survey of the land and imposed the tax in a prearranged sum based on the amount of cultivable land, the quantity of date palms and olive trees, and the number of people working on the land. Taxes were to be paid three times a year. Abuses were still rampant, but this was better than the old system; at least, if a drought or some other calamity occurred, taxes could be reduced or remitted. Although information is contradictory, it appears that religious communities other than the Zoroastrian one had extra taxes imposed on them from time to time. This was especially true of the growing Christian community, particularly in the time of Shāpūr II, after Christianity became the official religion of the Roman Empire.

Taxation

Religious communities became fixed under the Sāsānians, and Mesopotamia with its large Jewish and Christian populations experienced changes because of the shift in primary allegiance from the ruler to the head of the religious group. The exilarch of the Jews had legal and tax-collecting authority over the Jews of the Sāsānian empire. Mani, the founder of the Manichaean religion, was born in lower Mesopotamia, and his religion spread quickly both to the east and west, even before his death. In its homeland, Mesopotamia, it came under severe persecution by the priests of the Zoroastrian religion, who viewed Manichaeism as a dangerous heresy. Christianity, however, was viewed not as a heresy but as a separate religion, tolerated until it became the official religion of the enemy Roman Empire; Christians were then regarded as potential traitors to the Sāsānian state. The first large growth of Christianity in Mesopotamia came with the deportation and resettlement of Christians, especially from Antioch with its patriarch, during Shāpūr I's wars with the Romans. In a synod convened in 325, the metropolitan see of Ctesiphon was made supreme over other sees in the Sāsānian empire, and the first patriarch or catholicos was Papa. In 344 the first persecutions of Christians began; they lasted with varying degrees of severity until 422, when a treaty with the government ended the persecutions.

The earliest contemporary mention of Christians in Mesopotamia is in the inscriptions of Kartēr, the chief Zoroastrian priest after the reign of Shāpūr I. He mentions both Christians and Nazareans, possibly two kinds of Christians, Greek-speaking and Syriac-speaking, or two sects. It is not known which groups are meant, but it is known that followers of the Gnostic Christian leaders Bardesanes (Bar Daiṣān) and Marcion were active in Mesopotamia. Later, after the Nestorian church separated from the Monophysites, whose centre was in Antioch, the Nestorian church dominated Mesopotamia until the end of the Sāsānian dynasty, when the Monophysites were growing in numbers. After about 485 the Sāsānian government was satisfied that the Nestorian church in their domains was not loyal to Byzantium, and further persecutions were not state-inspired but rather prosecuted by the Zoroastrian clergy. At the end of the Sāsānian period, the Nestorians were fighting the Monophysites, now called Jacobites, more than the Zoroastrians. The Jacobites established many monasteries, especially in northern Mesopotamia, whereas the Nestorians were cool toward monasticism.

Ethnicity became less important than religious affiliation under the Sāsānians, who thus changed the social structure of Mesopotamia. The Arabs continued to grow in numbers, both as nomads and as settled folk, and Ara-

Growth of the Arab population

bic became widely spoken. King Nu'mān III of the Arab client kingdom of the Lakhmids of Al-Ḥīrah in southern Mesopotamia became a Christian in 580, but in 602 he was deposed by Khosrow II, who made the kingdom a province of the empire. This act removed a barrier against inroads by Arab tribesmen from the desert, and, after the union of Arabs in the peninsula under the banner of Islām, the fate of the Sāsānian empire was sealed. The Muslims, on the whole, were welcomed in Mesopotamia as deliverers from the foreign yoke of the Persians, but the conversion of the mass of the population to Islām did not proceed rapidly, mainly because of the well-organized Christian and Jewish communities. The arrival of Islām, of course, changed the history of Mesopotamia more than any other event in its history. (R.N.F.)

Metabolism

Living organisms are unique in that they can extract energy from their environments and use it to carry out activities such as movement, growth and development, and reproduction. But how do living organisms—or, their cells—extract energy from their environments, and how do cells use this energy to synthesize and assemble the components from which the cells are made?

The answers to these questions lie in the enzyme-mediated chemical reactions that take place in living matter (metabolism). Hundreds of coordinated, multistep reactions, fueled by energy obtained from nutrients and/or solar energy, ultimately convert readily available materials into the molecules required for growth and maintenance.

The physical and chemical properties of the components of living things dealt with in this article are found in the articles BIOCHEMICAL COMPONENTS OF ORGANISMS; CELLS; and PHOTOSYNTHESIS.

For coverage of related topics in the *Macropædia* and *Micropædia*, see the *Propædia*, section 322, and the *Index*.

The article is divided into the following sections:

A summary of metabolism

THE UNITY OF LIFE

At the cellular level of organization, the main chemical processes of all living matter are similar, if not identical. This is true for animals, plants, fungi, or bacteria; where variations occur (such as, for example, in the secretion of antibodies by some molds), the variant processes are but variations on common themes. Thus, all living matter is made up of large molecules called proteins, which provide support and coordinated movement, as well as storage and transport of small molecules, and, as catalysts, enable chemical reactions to take place rapidly and specifically under mild temperature, relatively low concentration, and neutral conditions (*i.e.*, neither acidic nor basic). Proteins are assembled from some 20 amino acids, and, just as the 26 letters of the alphabet can be assembled in specific ways to form words of various lengths and meanings, so may tens or even hundreds of the 20 amino-acid "letters" be joined to form specific proteins. Moreover, those portions of protein molecules involved in performing similar functions in different organisms often comprise the same sequences of amino acids.

Proteins

There is the same unity among cells of all types in the manner in which living organisms preserve their individuality and transmit it to their offspring. For example, hereditary information is encoded in a specific sequence of bases that make up the DNA (deoxyribonucleic acid) molecule in the nucleus of each cell. Only four bases are used in synthesizing DNA: adenine, guanine, cytosine, and thymine. Just as the Morse Code consists of three simple signals—a dash, a dot, and a space—the precise arrangement of which suffices to convey coded messages, so the precise arrangement of the bases in DNA contains and conveys the information for the synthesis and assembly of cell components. Some primitive life-forms, however, use RNA (ribonucleic acid; a nucleic acid differing from DNA in containing the sugar ribose instead of the sugar deoxyribose and the base uracil instead of the base thymine) in place of DNA as a primary carrier of genetic information. The replication of the genetic material in these organisms must, however, pass through a DNA phase. With minor exceptions, the genetic code used by all living organisms is the same.

The chemical reactions that take place in living cells are similar as well. Green plants use the energy of sunlight

to convert water (H_2O) and carbon dioxide (CO_2) to carbohydrates (sugars and starches), other organic (carbon-containing) compounds, and molecular oxygen (O_2). The process of photosynthesis requires energy, in the form of sunlight, to split one water molecule into one-half of an oxygen molecule (O_2; the oxidizing agent) and two hydrogen atoms (H; the reducing agent), each of which dissociates to one hydrogen ion (H^+) and one electron. Through a series of oxidation-reduction reactions, electrons (denoted e^-) are transferred from a donating molecule (oxidation), in this case water, to an accepting molecule (reduction) by a series of chemical reactions; this "reducing power" may be coupled ultimately to the reduction of carbon dioxide to the level of carbohydrate. In effect, carbon dioxide accepts and bonds with hydrogen, forming carbohydrates ($C_n[H_2O]_n$).

Living organisms that require oxygen reverse this process: they consume carbohydrates and other organic materials, using oxygen synthesized by plants to form water, carbon dioxide, and energy. The process that removes hydrogen atoms (containing electrons) from the carbohydrates and passes them to the oxygen is an energy-yielding series of reactions.

In plants, all but two of the steps in the process that converts carbon dioxide to carbohydrates are the same as those steps that synthesize sugars from simpler starting materials in animals, fungi, and bacteria. Similarly, the series of reactions that take a given starting material and synthesize certain molecules that will be used in other synthetic pathways are similar, or identical, among all cell types. From a metabolic point of view, the cellular processes that take place in a lion are only marginally different from those that take place in a dandelion.

BIOLOGICAL ENERGY EXCHANGES

Thermodynamics

The energy changes associated with physicochemical processes are the province of thermodynamics, a subdiscipline of physics. The first two laws of thermodynamics state, in essence, that energy can be neither created nor destroyed and that the effect of physical and chemical changes is to increase the disorder, or randomness (*i.e.*, entropy), of the universe. Although it might be supposed that biological processes—through which organisms grow in a highly ordered and complex manner, maintain order and complexity throughout their life, and pass on the instructions for order to succeeding generations—are in contravention of these laws, this is not so. Living organisms neither consume nor create energy: they can only transform it from one form to another. From the environment they absorb energy in a form useful to them; to the environment they return an equivalent amount of energy in a biologically less useful form. The useful energy, or free energy, may be defined as energy capable of doing work under isothermal conditions (conditions in which no temperature differential exists); free energy is associated with any chemical change. Energy less useful than free energy is returned to the environment, usually as heat. Heat cannot perform work in biological systems because all parts of cells have essentially the same temperature and pressure.

Free energy and heat

The carrier of chemical energy. At any given time, a neutral molecule of water dissociates into a hydrogen ion (H^+) and a hydroxide ion (OH^-), and the ions are continually re-forming into the neutral molecule. Under normal conditions (neutrality), the concentration of hydrogen ions (acidic ions) is equal to that of the hydroxide ions (basic ions); each are at a concentration of 10^{-7} moles per litre, which is described as a pH of 7.

All cells either are bounded by membranes or contain organelles that have membranes. These membranes do not permit water or the ions derived from water to pass into or out of the cells or organelles. In green plants, sunlight is absorbed by chlorophyll and other pigments in the chloroplasts of the cells, called photosystem II. As shown previously, when a water molecule is split by light energy, one-half of an oxygen molecule and two hydrogen atoms (which dissociate to two electrons and two hydrogen ions, H^+) are formed. When excited by sunlight, chlorophyll loses one electron to an electron carrier molecule but quickly recovers it from a hydrogen atom of the split water molecule, which sends H^+ into solution in the process. Two oxygen atoms come together to form a molecule of oxygen gas (O_2). The free electrons are passed to photosystem I, but, in doing so, an excess concentration of positively charged hydrogen ions (H^+) appears on one side of the membrane in the chloroplast, whereas an excess of negatively charged hydroxide ions (OH^-) builds up on the other side. The free energy released as H^+ ions move through a specific "pore" in the membrane, to equalize the concentrations of ions, is sufficient to make some biological processes work, such as the uptake of certain nutrients by bacteria and the rotation of the whiplike protein-based propellers that enable such bacteria to move. Equally important, however, is that this gradient across the membrane powers the formation of adenosine triphosphate (ATP) from inorganic phosphate (HPO_4^{2-}, abbreviated P_i) and adenosine diphosphate (ADP). It is ATP (Figure 1) that is the major carrier of biologically utilizable energy in all forms of living matter. The interrelationships of energy-yielding and energy-requiring metabolic reactions may be considered largely as processes that couple the formation of ATP with its breakdown.

Plant synthesis of ATP

Synthesis of ATP by green plants is similar to the synthesis of ATP that takes place in the mitochondria of animal, plant, and fungus cells, and in the plasma membranes of bacteria that use oxygen (or other inorganic electron acceptors, such as nitrate) to accept electrons from the removal of hydrogen atoms from a molecule of food (see below *The combustion of food materials: Biological energy transduction*). Through these processes most of the energy stored in food materials is released and converted into the molecules that fuel life processes. It must also be remembered, however, that many living organisms (usually

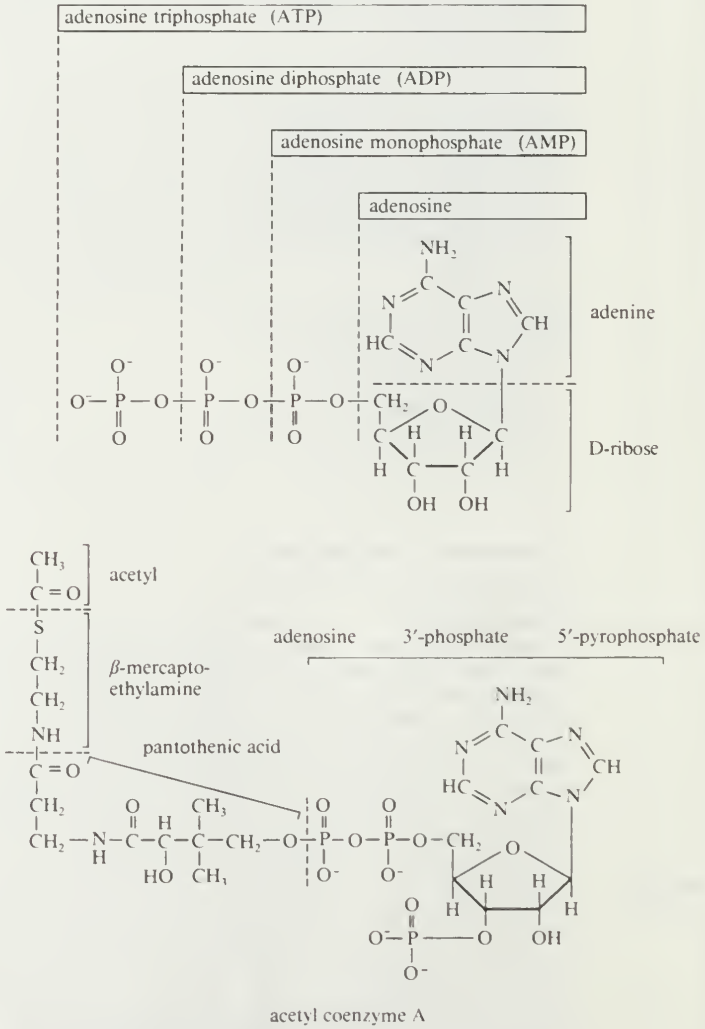

Figure 1: *Biological energy carriers.*
(Top) ATP, ADP, and AMP. (Bottom) Acetyl coenzyme A (acetyl CoA).

bacteria and protozoa) cannot tolerate oxygen; they form ATP from inorganic phosphate and ADP by substrate-level phosphorylations (the addition of a phosphate group) that do not involve the establishment and collapse of proton gradients across membranes. Such processes are discussed in detail below (*The fragmentation of complex molecules: The catabolism of glucose*). It must also be borne in mind that the fuels of life and the cellular "furnace" in which they are "burned" are made of the same types of material: if the fires burn too brightly, not only the fuel but also the furnace is consumed. It is therefore essential to release energy at small, discrete, readily utilizable intervals. The relative complexity of the catabolic pathways (by which food materials are broken down) and the complexity of the anabolic pathways (by which cell components are synthesized) reflect this need and offer the possibility for simple feedback systems to control the rate at which materials travel along these sequences of enzymic reactions.

Catabolism. *Formation of small molecules.* The release of chemical energy from food materials essentially occurs in three phases. In the first phase (phase I), the large molecules that make up the bulk of food materials are broken down into small constituent units: proteins are converted to the 20 or so different amino acids of which they are composed; carbohydrates (polysaccharides such as starch in plants and glycogen in animals) are degraded to sugars such as glucose; and fats (lipids) are broken down into fatty acids and glycerol. The amounts of energy liberated in phase I are relatively small: only about 0.6 percent of the free, or useful, energy of proteins and carbohydrates, and about 0.1 percent of that of fats, is released during this phase. Because this energy is liberated largely as heat, it cannot be utilized by the cell. The purpose of the reactions of phase I, which can be grouped under the term digestion and which, in animals, occur mainly in the intestinal tract and in tissues in which reserve materials are prepared, or mobilized, for energy production, is to prepare the foodstuffs for the energy-releasing processes.

Phase I

Incomplete oxidation. In the second phase of the release of energy from food (phase II), the small molecules produced in the first phase—sugars, glycerol, a number of fatty acids, and about 20 varieties of amino acids—are incompletely oxidized (in this sense, oxidation means the removal of electrons or hydrogen atoms), the end product being (apart from carbon dioxide and water) one of only three possible substances: the two-carbon compound acetate, in the form of a compound called acetyl coenzyme A (Figure 1); the four-carbon compound oxaloacetate; and the five-carbon compound α-oxoglutarate. The first, acetate in the form of acetyl coenzyme A, constitutes by far the most common product—it is the product of two-thirds of the carbon incorporated into carbohydrates and glycerol; all of the carbon in most fatty acids; and approximately half of the carbon in amino acids. The end product of several amino acids is α-oxoglutarate; that of a few others is oxaloacetate, which is formed either directly or indirectly (from fumarate). These processes, represented diagrammatically in Figure 2, show what happens in the bacterium *Escherichia coli,* but essentially similar processes occur in animals, plants, fungi, and other organisms capable of oxidizing their food materials wholly to carbon dioxide and water.

Phase II

Complete oxidation. Total oxidation of the relatively few products of phase II occurs in a cyclic sequence of chemical reactions known as the tricarboxylic acid (TCA) cycle, or the Krebs cycle, after its discoverer, Sir Hans Krebs; it represents phase III of energy release from foods. Each turn of this cycle (see below *The tricarboxylic acid [TCA] cycle*) is initiated by the formation of citrate, with six carbon atoms, from oxaloacetate (with four carbons) and acetyl coenzyme A; subsequent reactions result in the reformation of oxaloacetate and the formation of two molecules of carbon dioxide. The carbon atoms that go into the formation of carbon dioxide are no longer available to the cell. The concomitant stepwise oxidations—in which hydrogen atoms or electrons are removed from intermediate compounds formed during the cycle and, via a system of carriers, are transferred ultimately to oxygen to form water—are quantitatively the most important means of generating ATP from ADP and inorganic phosphate. These events are known as terminal respiration and oxidative phosphorylation (for details of this process, see below *Biological energy transduction*).

Phase III

Some microorganisms, incapable of completely converting their carbon compounds to carbon dioxide, release energy by fermentation reactions, in which the intermediate compounds of catabolic routes either directly or indirectly accept or donate hydrogen atoms. Such secondary changes in intermediate compounds result in considerably less energy being made available to the cell than occurs with the pathways that are linked to oxidative phosphorylation; however, fermentation reactions yield a large variety of commercially important products. Thus, for example, if the oxidation (removal of electrons or hydrogen atoms) of some catabolic intermediate is coupled to the reduction of pyruvate or of acetaldehyde derived from pyruvate, the products formed are lactic acid and ethyl alcohol, respectively.

Anabolism. Catabolic pathways effect the transformation of food materials into the interconvertible intermediates of the pathways shown in Figure 2. Anabolic pathways, on the other hand, are sequences of enzyme-catalyzed reactions in which the component building blocks of large molecules, or macromolecules (*e.g.,* proteins, carbohydrates, and fats), are constructed from the same intermediates. Thus, catabolic routes have clearly defined beginnings but no unambiguously identifiable end products; anabolic routes, on the other hand, lead to clearly distinguishable end products from diffuse beginnings. The two types of pathway are linked through reactions of phosphate transfer, involving ADP, AMP, and ATP as described above, and also through electron transfers, which enable reducing equivalents (*i.e.,* hydrogen atoms or electrons), which have been released during catabolic reactions, to be utilized for biosynthesis. But, although catabolic and anabolic pathways are closely linked, and although the overall effect of one type of route is obviously the opposite of the other, they have few steps in common. The anabolic pathway for the synthesis of a particular molecule generally starts from intermediate compounds quite different from those produced as a result of catabolism of that molecule; for example, microorganisms catabolize aromatic (*i.e.,* containing a ring, or cyclic, structure) amino acids to acetyl coenzyme A and an intermediate compound of the TCA cycle. The biosynthesis of these amino acids, however, starts with a compound derived from pyruvate and an

Anabolism versus catabolism

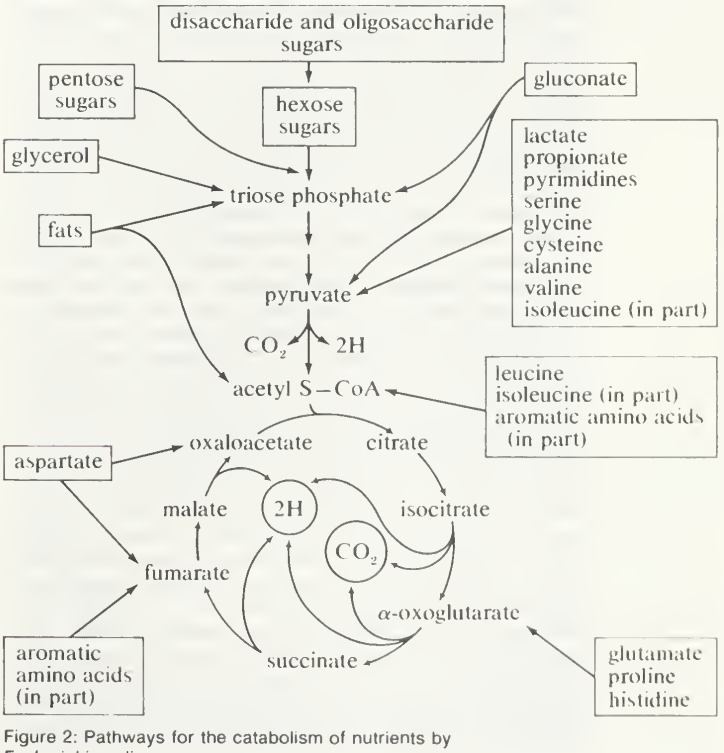

Figure 2: Pathways for the catabolism of nutrients by *Escherichia coli.*

intermediate compound of the metabolism of pentose (a general name for sugars with five carbon atoms). Similarly, histidine is synthesized from a pentose sugar but is catabolized to α-oxoglutarate.

Even in cases in which a product of catabolism is used in an anabolic pathway, differences emerge; thus, fatty acids, which are catabolized to acetyl coenzyme A, are synthesized not from acetyl coenzyme A directly but from a derivative of it, malonyl coenzyme A (see below *The biosynthesis of cell components: Lipid components*). Furthermore, even enzymes that catalyze apparently identical steps in catabolic and anabolic routes may exhibit different properties. In general, therefore, the way down (catabolism) is different from the way up (anabolism). These differences are important because they allow for the regulation of catabolic and anabolic processes in the cell.

Eukaryotic cells

In eukaryotic cells (*i.e.*, those with a well-defined nucleus, characteristic of organisms higher than bacteria) the enzymes of catabolic and anabolic pathways are often located in different cellular compartments. This also contributes to the manner of their cellular control; for example, the formation of acetyl coenzyme A from fatty acids, referred to above, occurs in animal cells in small sausage-shaped components, or organelles, called mitochondria, which also contain the enzymes for terminal respiration and for oxidative phosphorylation. The biosynthesis of fatty acids from acetyl coenzyme A, on the other hand, occurs in the cytoplasm.

INTEGRATION OF CATABOLISM AND ANABOLISM

Fine control. Possibly the most important means for controlling the flux of metabolites through catabolic and anabolic pathways, and for integrating the numerous different pathways in the cell, is through the regulation of either the activity or the synthesis of key (pacemaker) enzymes. It was recognized in the 1950s, largely from work with microorganisms, that pacemaker enzymes can interact with small molecules at more than one site on the surface of the enzyme molecule. The reaction between an enzyme and its substrate—defined as the compound with which the enzyme acts to form a product—occurs at a specific site on the enzyme known as the catalytic, or active, site; the proper fit between the substrate and the active site is an essential prerequisite for the occurrence of a reaction catalyzed by an enzyme (see BIOCHEMICAL COMPONENTS OF ORGANISMS). Interactions at other, so-called regulatory sites on the enzyme, however, do not result in a chemical reaction but cause changes in the shape of the protein; the changes profoundly affect the catalytic properties of the enzyme, either inhibiting or stimulating the rate of the reaction. Modulation of the activity of pacemaker enzymes may be effected by metabolites of the pathway in which the enzyme acts or by those of another pathway; the process may be described as a "fine control" of metabolism. Very small changes in the chemical environment thus produce important and immediate effects on the rates at which individual metabolic processes occur.

Most catabolic pathways are regulated by the relative proportions of ATP, ADP, and AMP in the cell. It is reasonable to suppose that a pathway that serves to make ATP available for energy-requiring reactions would be less active if sufficient ATP were already present, than if ADP or AMP were to accumulate. The relative amounts of the adenine nucleotides (*i.e.*, ATP, ADP, and AMP) thus modulate the overall rate of catabolic pathways. They do so by reacting with specific regulatory sites on pacemaker enzymes necessary for the catabolic pathways, which do not participate in the anabolic routes that effect the opposite reactions. Similarly, it is reasonable to suppose that many anabolic processes, which require energy, are inhibited by ADP or AMP; elevated levels of these nucleotides may be regarded therefore as cellular distress signals indicating a lack of energy.

Since one way in which anabolic pathways differ from catabolic routes is that the former result in identifiable end products, it is not unexpected that the pacemaker enzymes of many anabolic pathways—particularly those effecting the biosynthesis of amino acids and nucleotides—are regulated by the end products of these pathways or, in cases in which branching of pathways occurs, by end products of each branch. Such pacemaker enzymes usually act at the first step unique to a particular anabolic route. If branching occurs, the first step of each branch is controlled. By this so-called negative feedback system, the cellular concentrations of products determine the rates of their formation, thus ensuring that the cell synthesizes only as much of the products as it needs.

Coarse control. A second and less immediately responsive, or "coarse," control is exerted over the synthesis of pacemaker enzymes. The rate of protein synthesis reflects the activity of appropriate genes, which contain the information that directs all cellular processes. Coarse control is therefore exerted on genetic material rather than on enzymes. Preferential synthesis of a pacemaker enzyme is particularly required to accommodate a cell to major changes in its chemical milieu. Such changes occur in multicellular organisms only to a minor extent, so that this type of control mechanism is less important in animals than in microorganisms. In the latter, however, it may determine the ease with which a cell previously growing in one nutrient medium can grow after transfer to another. In cases in which several types of organism compete in the same medium for available carbon sources, the operation of coarse controls may well be decisive in ensuring survival.

Gene involvement

Alterations in the differential rates of synthesis of pacemaker enzymes in microorganisms responding to changes in the composition of their growth medium also manifest the properties of negative feedback systems. Depending on the nature of the metabolic pathway of which a pacemaker enzyme is a constituent, the manner in which the alterations are elicited may be distinguished. Thus, an increase in the rates at which enzymes of catabolic routes are synthesized results from the addition of inducers—usually compounds that exhibit some structural similarity to the substrates on which the enzymes act. A classic example of an inducible enzyme of this type is β-galactosidase. *Escherichia coli* growing in nutrient medium containing glucose do not utilize the milk sugar, lactose (glucose-4-β-D-galactoside); however, if the bacteria are placed in a growth medium containing lactose as the sole source of carbon, they synthesize β-galactosidase and can therefore utilize lactose. The reaction catalyzed by the enzyme is the hydrolysis (*i.e.*, breakdown involving water) of lactose to its two constituent sugars, glucose and galactose; the preferential synthesis of the enzyme thus allows the bacteria to use the lactose for growth and energy. Another characteristic of the process of enzyme induction is that it continues only as long as the inducer (in this case, lactose) is present; if cells synthesizing β-galactosidase are transferred to a medium containing no lactose, synthesis of β-galactosidase ceases, and the amount of the enzyme in the cells is diluted as they divide, until the original low level of the enzyme is reestablished.

In contrast, the differential rates of synthesis of pacemaker enzymes of anabolic routes are usually not increased by the presence of inducers. Instead, the absence of small molecules that act to repress enzyme synthesis accelerates enzyme formation. Similar to the fine control processes described above is the regulation by coarse control of many pacemaker enzymes of amino-acid biosynthesis. Like the end product inhibitors, the repressors in these cases also appear to be the amino-acid end products themselves.

It is useful to regard the acceleration of the enzyme-forming machinery as the consequence, metaphorically, of either placing a foot on the accelerator or removing it from the brake. Analysis of the mechanisms by which gene activity is controlled suggest, however, that the distinction between inducible and repressible enzymes may be more apparent than real (see below *Regulation of metabolism*).

THE STUDY OF METABOLIC PATHWAYS

Purpose

There are two main reasons for studying a metabolic pathway: (1) to describe, in quantitative terms, the chemical changes catalyzed by the component enzymes of the route; and (2) to describe the various intracellular controls that govern the rate at which the pathway functions.

Studies with whole organisms or organs can provide

information that one substance is converted to another and that this process is localized in a certain tissue; for example, experiments can show that urea, the chief nitrogen-containing end product of protein metabolism in mammals, is formed exclusively in the liver. They cannot reveal, however, the details of the enzymatic steps involved. Clues to the identity of the products involved, and to the possible chemical changes effected by component enzymes, can be provided in any of four ways involving studies with either whole organisms or tissues.

Identification of metabolites

First, under stress or the imbalances associated with diseases, certain metabolites may accumulate to a greater extent than normal. Thus, during the stress of violent exercise, lactic acid appears in the blood, while glycogen, the form in which carbohydrate is stored in muscle, disappears. Such observations do not, however, prove that lactic acid is a normal intermediate of glycogen catabolism; rather, they show only that compounds capable of yielding lactic acid are likely to be normal intermediates. Indeed, in the example, lactic acid is formed in response to abnormal circumstances and is not directly formed in the pathways of carbohydrate catabolism. On the other hand, the abnormal accumulation of pyruvic acid in the blood of vitamin B_1-deficient pigeons was a valuable clue to the role of this vitamin in the oxidation of pyruvate.

Second, the administration of metabolic poisons may lead to the accumulation of specific metabolites. If fluoroacetic acid or fluorocitric acid is ingested by animals, for example, citric acid accumulates in the liver. This correctly suggests that fluorocitric acid administered as such, or formed from fluoroacetic acid via the tricarboxylic acid (TCA) cycle, inhibits an enzyme of citrate oxidation.

Third, the fate of any nutrient—indeed, often the fate of a particular chemical group or atom in a nutrient—can be followed with relative ease by administering the nutrient labeled with an isotope. Isotopes are forms of an element that are chemically indistinguishable from each other but differ in physical properties.

The use of a nonradioactive isotope of nitrogen in the 1930s first revealed the dynamic state of body constituents. It had previously been believed that the proteins of tissues are stable once formed, disappearing only with the death of the cell. By feeding amino acids labeled with isotopic nitrogen to rats, it was discovered that the isotope was incorporated into many of the amino acids found in proteins of the liver and the gut, even though the total protein content of these tissues did not change. This suggested that the proteins of these tissues exist in a dynamic steady state, in which relatively high rates of synthesis are counterbalanced by equal rates of degradation. Thus, although the average liver cell has a life-span of several months, half of its proteins are synthesized and degraded every five to six days. On the other hand, the proteins of the muscle or the brain, tissues that (unlike the gut or liver) need not adjust to changes in the chemical composition of their milieu, do not turn over as rapidly. The high rates of turnover observed in liver and gut tissues indicate that the coarse controls, exerted through the onset and cessation of synthesis of pacemaker enzymes, do occur in animal cells.

Rate of protein turnover

Finally, genetically altered organisms (mutants) fail to synthesize certain enzymes in an active form. Such defects, if not lethal, result in the accumulation and excretion of the substrate of the defective enzyme; in normal organisms, the substrate would not accumulate, because it would be acted upon by the enzyme. The significance of this observation was first realized in the early 20th century when the phrase "inborn errors of metabolism" was used to describe hereditary conditions in which a variety of amino acids and other metabolites are excreted in the urine (see below *Metabolic diseases*). In microorganisms, in which it is relatively easy to cause genetic mutations and to select specific mutants, this technique has been very useful. In addition to their utility in the unraveling of metabolic pathways, the use of mutants in the early 1940s led to the postulation of the one gene-one enzyme hypothesis by the Nobel Prize winners George W. Beadle and Edward L. Tatum; their discoveries opened the field of biochemical genetics and first revealed the nature of the fine controls of metabolism.

Because detailed information about the mechanisms of component enzymatic steps in any metabolic pathway cannot be obtained from studies with whole organisms or tissues, various techniques have been developed for studying these processes—*e.g.,* sliced tissues, and homogenates and cell-free extracts, which are produced by physical disruption of the cells and the removal of cell walls and other debris. The sliced-tissue technique was successfully used by the Nobel Prize winner Sir Hans Krebs in his pioneer studies in the early 1930s on the mechanism of urea formation in the liver. Measurements were made of the stimulating effects of small quantities of amino acids on both the rate of oxygen uptake and the amount of oxygen taken up; the amino acids were added to liver slices bathed in a nutrient medium. Such measurements revealed the cyclic nature of the process; specific amino acids acted as catalysts, stimulating respiration to an extent greater than expected from the quantities added. This was because the added material had been re-formed in the course of the cycle (see below *The catabolism of proteins: Disposal of nitrogen*).

The use of homogenates

Homogenates of tissue are useful in studying metabolic processes because permeability barriers that may prevent ready access of external materials to cell components are destroyed. The tissue is usually minced, blended, or otherwise disrupted in a medium that is suitably buffered to maintain the normal acid–base balance of the tissue, and contains the ions required for many life processes, chiefly sodium, potassium, and magnesium. The tissue is either used directly—as was done by Krebs in elucidating, in 1937, the TCA cycle from studies of the respiration of minced pigeon breast muscle—or fractionated (*i.e.,* broken down) further. If the latter procedure is followed, homogenization is often carried out in a medium containing a high concentration of the sugar sucrose, which provides a milieu favourable for maintaining the integrity of cellular components. The components are recovered by careful spinning in a centrifuge, at a series of increasing speeds. It is thus possible to obtain fractions containing predominantly one type of organelle: nuclei (and some unbroken cells); mitochondria, lysosomes, and microbodies; microsomes (*i.e.,* ribosomes and endoplasmic reticulum fragments); and—after prolonged centrifugation at forces in excess of 100,000 times gravity—a clear liquid that represents the soluble fraction of the cytoplasm. The fractions thus obtained can be further purified and tested for their capacity to carry out a given metabolic step or steps. This procedure was used to show that isolated mitochondria catalyze the oxidation reactions of the TCA cycle and that these organelles also contain the enzymes of fatty acid oxidation. Similarly, isolated ribosomes are used to study the pathway and mechanism of protein synthesis.

The final step in elucidating a reaction in a metabolic pathway includes isolation of the enzyme involved. The rate of the reaction and the factors that control the activity of the enzyme are then measured.

It should be emphasized that biochemists realize that studies on isolated and highly purified systems, such as those briefly described above, can do no more than approximate biological reality. The identification of the fine and coarse controls of a metabolic pathway, and (when appropriate) other influences on that pathway, must ultimately involve the study of the pathway in the whole cell or organism. Although some techniques have proved adequate for relating findings in the test tube to the situation in living organisms, study of the more complex metabolic processes, such as those involved in differentiation and development, may require the elaboration of new experimental approaches.

The fragmentation of complex molecules

Food materials must undergo oxidation in order to yield biologically useful energy. Oxidation does not necessarily involve oxygen, although it must involve the transfer of electrons from a donor molecule to a suitable acceptor molecule; the donor is thus oxidized and the recipient reduced. Many microorganisms either must live in the absence of oxygen (*i.e.,* are obligate anaerobes) or can live in

its presence or its absence (*i.e.*, are facultative anaerobes).

Fermentations

If no oxygen is available, the catabolism of food materials is effected via fermentations, in which the final acceptor of the electrons removed from the nutrient is some organic molecule, usually generated during the fermentation process. There is no net oxidation of the food molecule in this type of catabolism; that is, the overall oxidation state of the fermentation products is the same as that of the starting material.

Organisms that can use oxygen as a final electron acceptor also use many of the steps in the fermentation pathways in which food molecules are broken down to smaller fragments; these fragments, instead of serving as electron acceptors, are fed into the TCA cycle, the pathway of terminal respiration.

In this cycle all of the hydrogen atoms (H) or electrons (e^-) are removed from the fragments and are channeled through a series of electron carriers, ultimately to react with oxygen (O; see below *Energy conservation*). All carbon atoms are eliminated as carbon dioxide (CO_2) in this process. The sequence of reactions involved in the catabolism of food materials may thus be conveniently considered in terms of an initial fragmentation (fermentation), followed by a combustion (respiration) process.

THE CATABOLISM OF GLUCOSE

Glycolysis. *The transformation of glucose.* Quantitatively, the most important source of energy for cellular processes is the six-carbon sugar glucose ($C_6H_{12}O_6$). Two structures of glucose are shown in Figure 3, in which the carbon atoms are numbered. (See BIOCHEMICAL COMPONENTS OF ORGANISMS for a discussion of the chemical nature of glucose and other carbohydrates.) Glucose is made available to animals through the hydrolysis of polysaccharides, such as glycogen and starch, the process being catalyzed by digestive enzymes. In animals, the sugar thus set free passes from the gut into the bloodstream and from there into the cells of the liver and other tissues. In microorganisms, of course, no such specialized tissues are involved.

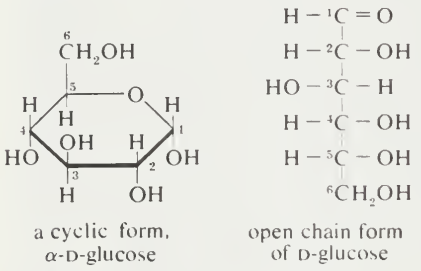

Figure 3: The structure of α-D-glucose.

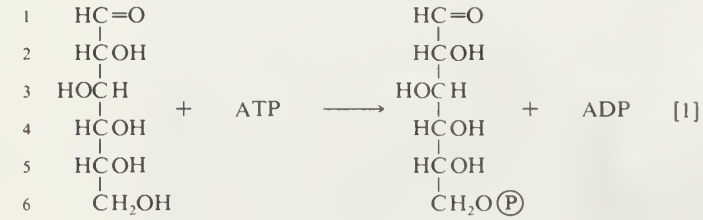
The fermentative phase of glucose catabolism (glycolysis) involves several enzymes; the action of each is summarized below. In living cells many of the compounds that take part in metabolism exist as negatively charged moieties, or anions, and are named as such in most of this article; *e.g.*, pyruvate, oxaloacetate.

In order to obtain a net yield of ATP from the catabolism of glucose, it is first necessary to invest ATP. During step [1] the alcohol group at position 6 of the glucose molecule readily reacts with the terminal phosphate group of ATP, forming glucose 6-phosphate and ADP. For convenience, the phosphoryl group (PO_3^{2-}) is represented by Ⓟ. Because the decrease in free energy is so large, this reaction is virtually irreversible under physiological conditions.

The formation of glucose 6-phosphate

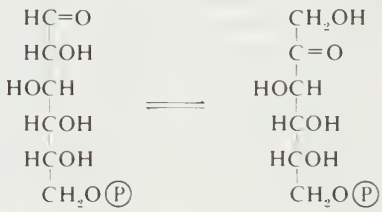


[1]

In animals, this phosphorylation of glucose, which yields glucose 6-phosphate, is catalyzed by two different enzymes. In most cells a hexokinase with a high affinity for glucose—*i.e.*, only small amounts of glucose are necessary for enzymatic activity—effects the reaction. In addition, the liver contains a glucokinase, which requires a much greater concentration of glucose before it reacts. Glucokinase functions only in emergencies, when the concentration of glucose in the blood rises to abnormally high levels.

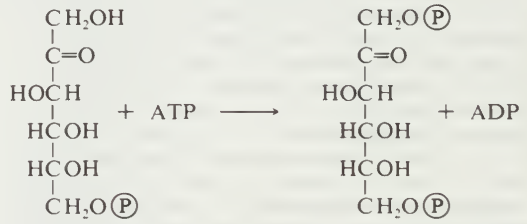
Certain facultative anaerobic bacteria also contain hexokinases but apparently do not use them to phosphorylate glucose. In such cells, external glucose can be utilized only if it is first phosphorylated to glucose 6-phosphate via a system linked to the cell membrane that involves a compound called phosphoenolpyruvate (formed in step [9] of glycolysis), which serves as an obligatory donor of the phosphate group; *i.e.*, ATP cannot serve as the phosphate donor in the reaction.

The reaction in which glucose 6-phosphate is changed to fructose 6-phosphate is catalyzed by phosphoglucoisomerase [2]. In the reaction, a secondary alcohol group (−CHOH) at the second carbon atom is oxidized to a keto-group (*i.e.*, −C=O), and the aldehyde group (−CHO) at the first carbon atom is reduced to a primary alcohol group ($-CH_2OH$). Reaction [2] is readily reversible, as is indicated by the double arrows.



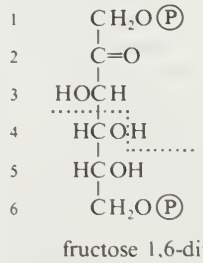
[2]

The formation of the alcohol group at the first carbon atom permits the repetition of the reaction effected in step [1]; that is, a second molecule of ATP is invested. The product is fructose 1,6-diphosphate [3]. Again, as in the hexokinase reaction, the decrease in free energy of the reaction, which is catalyzed by phosphofructokinase, is sufficiently large to make this reaction virtually irreversible under physiological conditions; ADP is also a product.

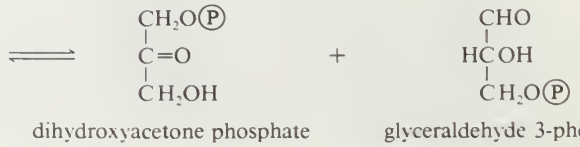


[3]

The first three steps of glycolysis have thus transformed an asymmetrical sugar molecule, glucose, into a symmetri-



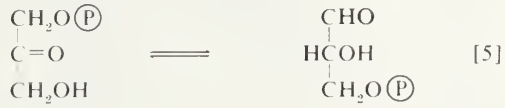
[4]



cal form, fructose 1,6-diphosphate, containing a phosphoryl group at each end; the molecule next is split into two smaller fragments that are interconvertible. This elegant simplification is achieved via steps [4] and [5], which are described below.

Aldol condensation

The aldolase reaction. In [4], an enzyme catalyzes the breaking apart of the six-carbon sugar fructose 1,6-diphosphate into two three-carbon fragments. The molecule is split between carbons 3 and 4. Reversal of this cleavage—*i.e.*, the formation of a six-carbon compound from two three-carbon compounds—is possible. Because the reverse reaction is an aldol condensation—*i.e.*, an aldehyde (glyceraldehyde 3-phosphate) combines with a ketone (dihydroxyacetone phosphate)—the enzyme is commonly called aldolase. The two three-carbon fragments produced in step [4], dihydroxyacetone phosphate and glyceraldehyde 3-phosphate, are also called triose phosphates. They are readily converted to each other by a process [5] analogous to that in step [2]. The enzyme that catalyzes the interconversion [5] is triose phosphate isomerase, a different enzyme than that catalyzing step [2].

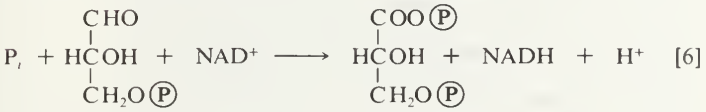


[5]

dihydroxyacetone phosphate glyceraldehyde 3-phosphate

Conversion of energy of oxidation into ATP

The formation of ATP. The second stage of glucose catabolism comprises reactions [6] through [10], in which a net gain of ATP is achieved through the oxidation of one of the triose phosphate compounds formed in step [5]. One molecule of glucose forms two molecules of the triose phosphate; both three-carbon fragments follow the same pathway, and steps [6] through [10] must occur twice to complete the glucose breakdown.

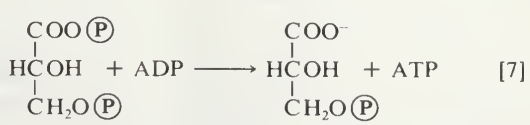


[6]

glyceraldehyde 3-phosphate 1,3-diphosphoglycerate

Step [6], in which glyceraldehyde 3-phosphate is oxidized, is one of the most important reactions in glycolysis. It is during this step that the energy liberated during oxidation of the aldehyde group (−CHO) is conserved in the form of a high-energy phosphate compound; namely, as 1,3-diphosphoglycerate, an anhydride of a carboxylic acid and phosphoric acid. The hydrogen atoms or electrons removed from the aldehyde group during its oxidation are accepted by a coenzyme (so called because it functions in conjunction with an enzyme) involved in hydrogen or electron transfer; the coenzyme, nicotinamide adenine dinucleotide (NAD^+), is reduced to form $NADH + H^+$ in the process. The NAD^+ thus reduced is bound to the enzyme glyceraldehyde 3-phosphate dehydrogenase, catalyzing the overall reaction, step [6].

The 1,3-diphosphoglycerate produced in step [6] reacts with ADP in a reaction catalyzed by phosphoglycerate kinase, with the result that one of the two phosphoryl groups is transferred to ADP to form ATP and 3-phosphoglycerate. This reaction [7] is highly exergonic (*i.e.*, it proceeds with a loss of free energy); as a result, the oxidation of glyceraldehyde 3-phosphate, step [6], is irreversible. In summary, the energy liberated during oxidation of an aldehyde group (−CHO in glyceraldehyde 3-phosphate) to a carboxylic acid group ($-COO^-$ in 3-phosphoglycerate) is conserved as the phosphate bond energy in ATP during steps [6] and [7]. This step occurs twice for each molecule of glucose; thus the initial investment of ATP in steps [1] and [3] is recovered.



[7]

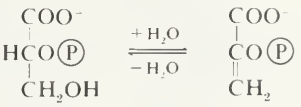
1,3-diphosphoglycerate 3-phosphoglycerate

[8]

3-phosphoglycerate 2-phosphoglycerate

The 3-phosphoglycerate in step [7] now forms 2-phosphoglycerate, in a reaction catalyzed by phosphoglyceromutase [8]. During step [9] the enzyme enolase reacts with 2-phosphoglycerate to form phosphoenolpyruvate (PEP), water being lost from 2-phosphoglycerate in the process. Phosphoenolpyruvate acts as the second source of ATP in glycolysis. The transfer of the phosphate group from PEP to ADP, catalyzed by pyruvate kinase [10], is also highly exergonic and is thus virtually irreversible under physiological conditions.

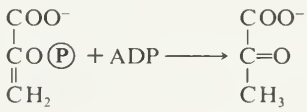
A second source of ATP



[9]

2-phosphoglycerate phosphoenolpyruvate

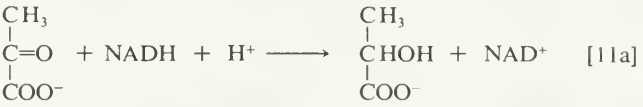
Reaction [10] occurs twice for each molecule of glucose entering the glycolytic sequence; thus the net yield is two molecules of ATP for each six-carbon sugar. No further molecules of glucose can enter the glycolytic pathway, however, until the $NADH + H^+$ produced in step [6] is reoxidized to NAD^+. In anaerobic systems this means that electrons must be transferred from ($NADH + H^+$) to some



[10]

phosphoenolpyruvate pyruvate

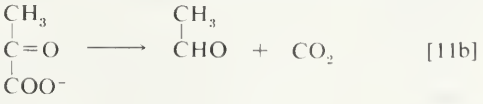
organic acceptor molecule, which thus is reduced in the process. Such an acceptor molecule could be the pyruvate formed in reaction [10]. In certain bacteria (*e.g.*, so-called lactic acid bacteria) or in muscle cells functioning vigorously in the absence of adequate supplies of oxygen,



[11a]

pyruvate lactate

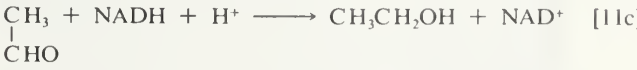
pyruvate is reduced to lactate via a reaction catalyzed by lactate dehydrogenase (reaction [11a]); *i.e.*, NADH gives up its hydrogen atoms or electrons to pyruvate, and lactate and NAD^+ are formed. Alternatively, in organisms such as brewers' yeast, pyruvate is first decarboxylated to form



[11b]

pyruvate acetaldehyde

acetaldehyde and carbon dioxide in a reaction catalyzed by pyruvate decarboxylase [11b]; acetaldehyde then is reduced (by $NADH + H^+$) in a reaction catalyzed by alcohol dehydrogenase [11c], yielding ethanol and oxidized coenzyme (NAD^+).



[11c]

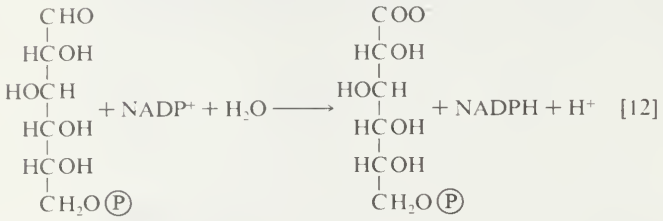
acetaldehyde ethanol

Many variations of reaction [11] occur in nature. In the heterolactic (mixed lactic acid) fermentations carried out by some microorganisms, a mixture of reactions [11a, b, and c] regenerates NAD^+ and results in the production, for each molecule of glucose fermented, of a molecule each of lactate, ethanol, and carbon dioxide. In other types

of fermentation, the end products may be derivatives of acids such as propionic, butyric, acetic, and succinic; decarboxylated materials derived from them (*e.g.*, acetone); or compounds such as glycerol.

The oxidation of glucose 6-phosphate

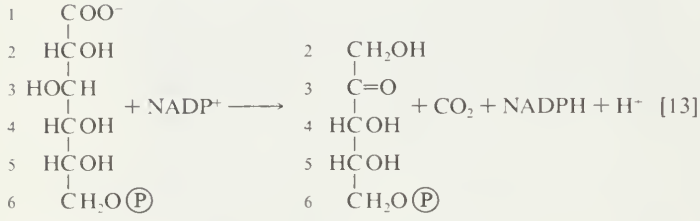
The phosphogluconate pathway. Many cells possess, in addition to all or part of the glycolytic pathway that comprises reactions [1] through [11], other pathways of glucose catabolism that involve, as the first unique step, the oxidation of glucose 6-phosphate [12] instead of the formation of fructose 6-phosphate [2]. This is the phosphogluconate pathway, or pentose phosphate cycle. During reaction [12], hydrogen atoms or electrons are removed from the carbon atom at position 1 of glucose 6-phosphate in a reaction catalyzed by glucose 6-phosphate dehydrogenase. The product of the reaction is 6-phosphogluconate.



[12]

glucose 6-phosphate 6-phosphogluconate

The reducing equivalents (hydrogen atoms or electrons) are accepted by nicotine adenine dinucleotide phosphate ($NADP^+$), a coenzyme similar to but not identical with NAD^+. A second molecule of $NADP^+$ is reduced as 6-phosphogluconate is further oxidized; the reaction is catalyzed by 6-phosphogluconate dehydrogenase [13]. The products of the reaction also include ribulose 5-phosphate and carbon dioxide. (The numbers at the carbon atoms in step [13] indicate that carbon 1 of 6-phosphogluconate forms carbon dioxide.)



[13]

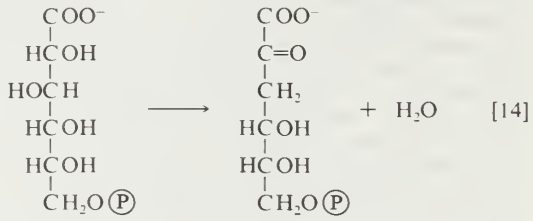
6-phosphogluconate ribulose 5-phosphate

Ribulose 5-phosphate can undergo a series of reactions in which two-carbon and three-carbon fragments are interchanged between a number of sugar phosphates; this sequence of events can lead to the formation of two molecules of fructose 6-phosphate and one of glyceraldehyde 3-phosphate from three molecules of ribulose 5-phosphate (*i.e.*, the conversion of three molecules with five carbons to two with six and one with three). Although the cycle, which is outlined in Figure 4, is the main pathway in microorganisms for fragmentation of pentose sugars, it is not of major importance as a route for the oxidation of glucose. Its primary purpose in most cells is to generate reducing power in the cytoplasm, in the form of reduced $NADP^+$. This function is especially prominent in tissues—such as the liver, mammary gland, fat tissue, and the cortex (outer region) of the adrenal gland—that actively carry out the biosynthesis of fatty acids and other fatty substances (*e.g.*, steroids). A second function of reactions [12] and [13] is to generate from glucose 6-phosphate the pentoses that are used in the synthesis of nucleic acids (see below *The biosynthesis of cell components*).

In photosynthetic organisms, some of the reactions of the phosphogluconate pathway are part of the major route for the formation of sugars from carbon dioxide; in this case, the reactions occur in a direction opposite to that in which they occur in nonphotosynthetic tissues (see PHOTOSYNTHESIS).

Alternative route

A different route for the catabolism of glucose also involves 6-phosphogluconate; it is of considerable importance in microorganisms lacking some of the enzymes necessary for glycolysis. In this route, 6-phosphogluconate (derived from glucose via steps [1] and [12]) is not oxidized to ribulose 5-phosphate via reaction [13] but, in an enzyme-catalyzed reaction [14], loses water, forming the compound 2-keto-3-deoxy-6-phosphogluconate (KDPG).



[14]

6-phosphogluconate KDPG

This is then split into pyruvate and glyceraldehyde-3-phosphate [15], both of which are intermediates of the glycolytic pathway.

THE CATABOLISM OF SUGARS OTHER THAN GLUCOSE

The main storage carbohydrate of animal cells is glycogen, in which chains of glucose molecules—linked end-to-end, the C1 position of one glucose being linked to the C4 position of the adjacent one—are joined to each other by occasional linkages between a carbon at position 1 on one glucose and a carbon at position 6 on another. Two enzymes cooperate in releasing glucose molecules from glycogen. Glycogen phosphorylase catalyzes the splitting of the 1,4-bonds by adding the elements of phosphoric acid

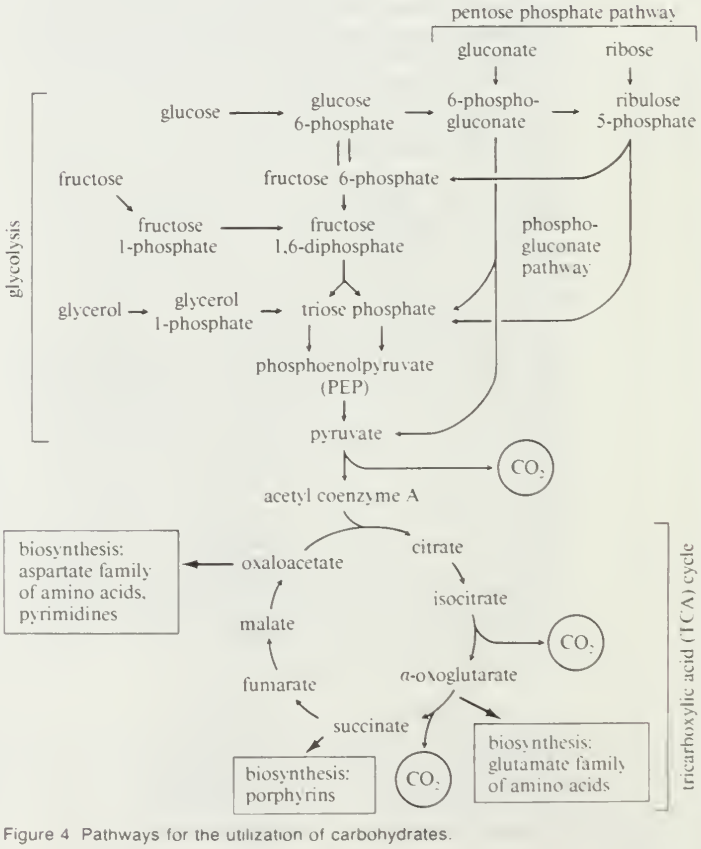

Figure 4 Pathways for the utilization of carbohydrates.

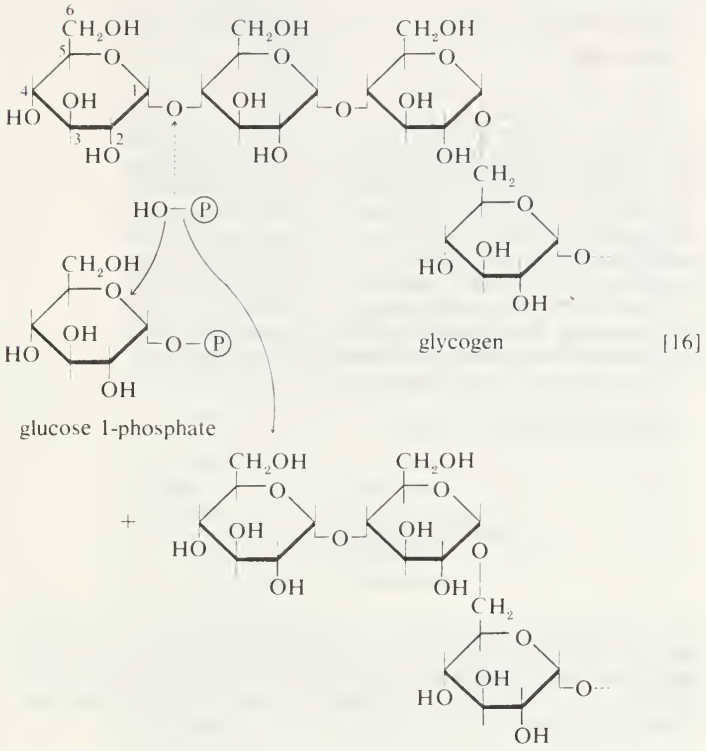
at the point shown by the broken arrow in [16], rather than water, as in the digestive hydrolysis of polysaccharides such as glycogen and starch. The products of [16] are glucose 1-phosphate and chains of sugar molecules shortened by one unit; the chains are degraded further by repetition of step [16]. When a bridge linking two chains, at C1 and C6 carbon atoms of adjacent glucose units, is reached, it is hydrolyzed in a reaction involving the enzyme α $(1 \rightarrow 6)$ glucosidase. After the two chains are separated, reaction [16] can occur again. The glucose 1-phosphate thus formed from glycogen or, in plants, from starch, is converted to glucose 6-phosphate by phosphoglucomutase [78], which catalyzes a reaction very similar to that effected in step [8] of glycolysis; glucose 6-phosphate can then undergo further catabolism via glycolysis [2–10] or via either of the routes involving formation of 6-phosphogluconate [12].

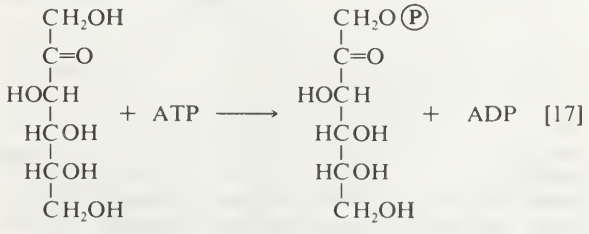


glycogen [16]

glucose 1-phosphate

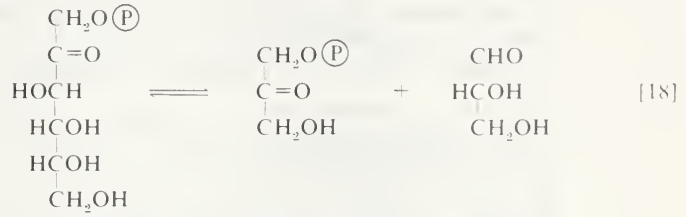
Other sugars encountered in the diet are likewise transformed to products that are intermediates of central metabolic pathways. Lactose, or milk sugar, is composed of one molecule of galactose linked to one molecule of glucose. Sucrose, the common sugar of cane or beet, is made up of glucose linked to fructose. Both sucrose and lactose are hydrolyzed to glucose and fructose or galactose, respectively. Glucose is utilized as already described, but special reactions must occur before the other sugars can enter the catabolic routes. Galactose, for example, is phosphorylated in a manner analogous to step [1] of glycolysis. The reaction, catalyzed by a galactokinase, results in the formation of galactose 1-phosphate; this product is transformed to glucose 1-phosphate by a sequence of reactions requiring as a coenzyme uridine triphosphate (UTP). Fructose may also be phosphorylated in animal cells through the action of hexokinase [1], in which case fructose 6-phosphate is the product, or in liver tissue via a fructokinase that gives rise to fructose 1-phosphate [17]. Adenosine triphosphate supplies the phosphate group in both cases.

Fragmentation of lactose and sucrose



fructose fructose 1-phosphate

Fructose 1-phosphate is also formed when facultative anaerobic microorganisms use fructose as a carbon source for growth; in this case, however, the source of the phosphate is phosphoenolpyruvate rather than ATP. Fructose 1-phosphate can be catabolized by one of two routes. In the liver, it is split by an aldolase enzyme [18] abundant in that tissue (but lacking in muscle); the products are dihydroxyacetone phosphate and glyceraldehyde. It will be recalled that dihydroxyacetone phosphate is an intermediate compound of glycolysis. Although glyceraldehyde is not an intermediate of glycolysis, it can be converted to one (glyceraldehyde 3-phosphate) in a reaction involving the conversion of ATP to ADP.



fructose 1-phosphate dihydroxyacetone phosphate glyceraldehyde

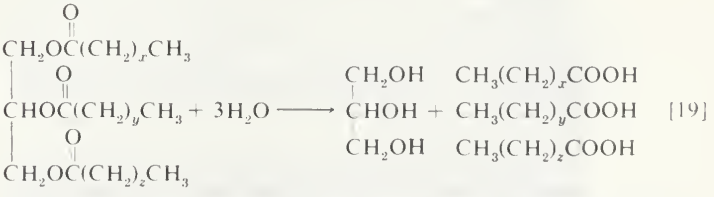
In many organisms other than mammals, fructose 1-phosphate does not have to undergo reaction [18] in order to enter central metabolic routes. Instead, a fructose 1-phosphate kinase, distinct from the phosphofructokinase that catalyzes step [3] of glycolysis, effects the direct conversion of fructose 1-phosphate and ATP to fructose 1,6-diphosphate and ADP.

THE CATABOLISM OF LIPIDS (FATS)

Although carbohydrates are the major fuel for most organisms, fatty acids are also a very important energy source. In vertebrates at least half of the oxidative energy used by the liver, kidneys, heart muscle, and resting skeletal muscle is derived from the oxidation of fatty acids; in fasting or hibernating animals or in migrating birds, fat is virtually the sole source of energy.

Triglycerides

Neutral fats or triglycerides, the major components of storage fats in plant and animal cells, consist of the alcohol glycerol linked to three molecules of fatty acids. Before a molecule of neutral fat can be metabolized, it must be hydrolyzed to its component parts. Hydrolysis [19] is effected by intracellular enzymes or gut enzymes, and forms phase I of fat catabolism. Letters x, y, and z represent the number of $-CH_2-$ groups in the fatty acid molecules.

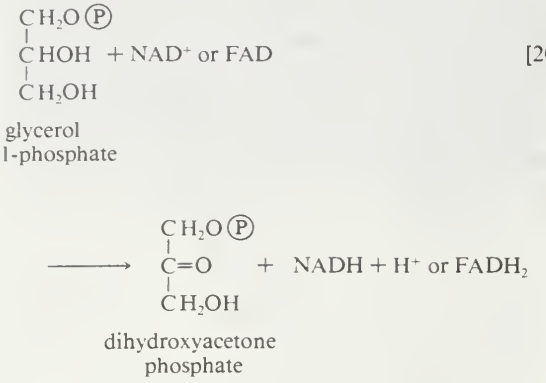


triglyceride glycerol fatty acids

As is apparent from [19], the three molecules of fatty acid released from the triglyceride need not be identical; a fatty acid usually contains 16 or 18 carbon atoms but may also be unsaturated; that is, containing one or more double bonds ($-CH=CH-$). Only the fate of saturated fatty acids, of the type $CH_3(CH_2)_nCOOH$ (n most commonly is an even number), is dealt with here.

Fate of glycerol. It requires but two reactions to channel glycerol into a catabolic pathway (see Figure 2). In a reaction catalyzed by glycerolkinase, ATP is used to phosphorylate glycerol; the products are glycerol 1-phosphate and ADP. Glycerol 1-phosphate is then oxidized to dihydroxyacetone phosphate [20], an intermediate of glycolysis. The reaction is catalyzed by either a soluble (cytoplasmic) enzyme, glycerolphosphate dehydrogenase, or a similar enzyme present in the mitochondria. In addition to their different locations, the two dehydrogenase enzymes differ in that a different coenzyme accepts the electrons removed

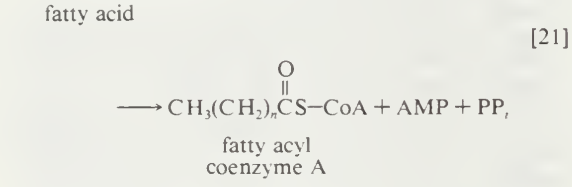
from glycerol 1-phosphate. In the case of the cytoplasmic enzyme, NAD^+ accepts the electrons (and is reduced to $NADH + H^+$); in the case of the mitochondrial enzyme, flavin adenine dinucleotide (FAD) accepts the electrons (and is reduced to $FADH_2$).



[20]

Fate of fatty acids. As with sugars, the release of energy from fatty acids necessitates an initial investment of ATP. A problem unique to fats is a consequence of the low solubility in water of most fatty acids. Their catabolism requires mechanisms that fragment them in a controlled and stepwise manner. The mechanism involves a coenzyme for the transfer of an acyl group (*e.g.*, $CH_3\overset{|}{C}{=}O$), namely, coenzyme A. The functional portion of this complex molecule is the sulfhydryl (−SH) group at one end. The coenzyme is often identified as CoA−SH (see step [21]). The organized and stepwise degradation of fatty acids linked to coenzyme A is ensured because the necessary enzymes are sequestered in particulate structures. In microorganisms these enzymes are associated with cell membranes, and in higher organisms with mitochondria.

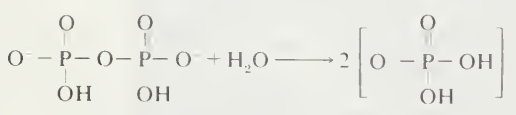
Coenzyme A and the fragmentation of fats



[21]

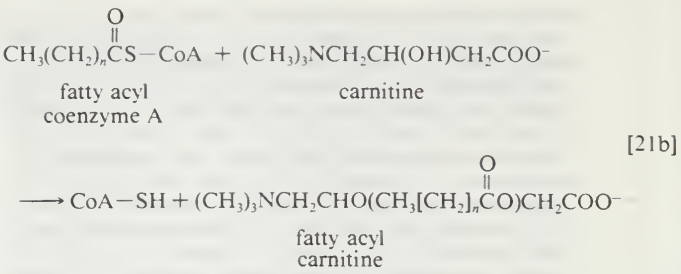
Fatty acids are linked to coenzyme A (CoA−SH) in one of two main ways. In higher organisms, enzymes in the cytoplasm called thiokinases catalyze the linkage of fatty acids with CoA−SH to form a compound that can be called a fatty acyl coenzyme A [21]. This step requires ATP, which is split to AMP and inorganic pyrophosphate (PP_i) in the process.

In this series of reactions, n indicates the number of hydrocarbon units ($-CH_2-$) in the molecule. Because most tissues contain highly active pyrophosphatase enzymes [21a], which catalyze the virtually irreversible hydrolysis of inorganic pyrophosphate (PP_i) to two molecules of inorganic phosphate (P_i), reaction [21] proceeds overwhelmingly to completion; *i.e.*, from left to right.



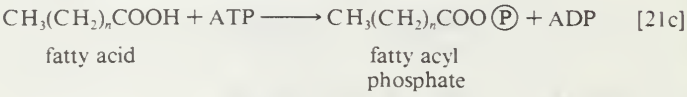
[21a]

Although fatty acids are activated in this way, the acyl coenzyme A derivatives that are formed must be transported to the enzyme complex that effects their oxidation. Activation occurs in the cytoplasm, but, in animal cells, oxidation takes place in the mitochondria. The transfer of fatty acyl coenzyme A across the mitochondrial membrane is effected by the enzyme carnitine, a nitrogen-containing small hydroxy acid of the formula $(CH_3)_3NCH_2CH(OH)CH_2COO^-$. The −OH group within



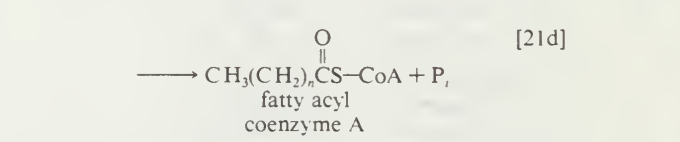
[21b]

the carnitine molecule accepts the acyl group of fatty acyl coenzyme A, forming acyl carnitine, which can cross the inner membrane of the mitochondrion and there return the acyl group to coenzyme A.



[21c]

These reactions are catalyzed by the enzyme carnitine acyl transferase. Defects in this enzyme or in the carnitine carrier are inborn errors of metabolism. In obligate anaerobic bacteria the linkage of fatty acids to coenzyme A may require the formation of a fatty acyl phosphate, *i.e.*, the phosphorylation of the fatty acid using ATP; ADP is also a product [21c]. The fatty acyl moiety $[CH_3(CH_2)_nCOO^-]$ is then transferred to coenzyme A [21d], forming a fatty acyl coenzyme A compound and P_i. In either case, it is the fatty acyl coenzyme A molecules that are fragmented in the sequence of events summarized in Figure 5.



[21d]

Initially (step [22], Figure 5) two hydrogen atoms are lost from the fatty acyl coenzyme A, resulting in the formation of an unsaturated fatty acyl coenzyme A (*i.e.*, with a double bond, $-CH{=}CH-$) between the α- and β-carbons of the acyl moiety. (The α-carbon is the one closest to

Unsaturated fatty acyl coenzyme A

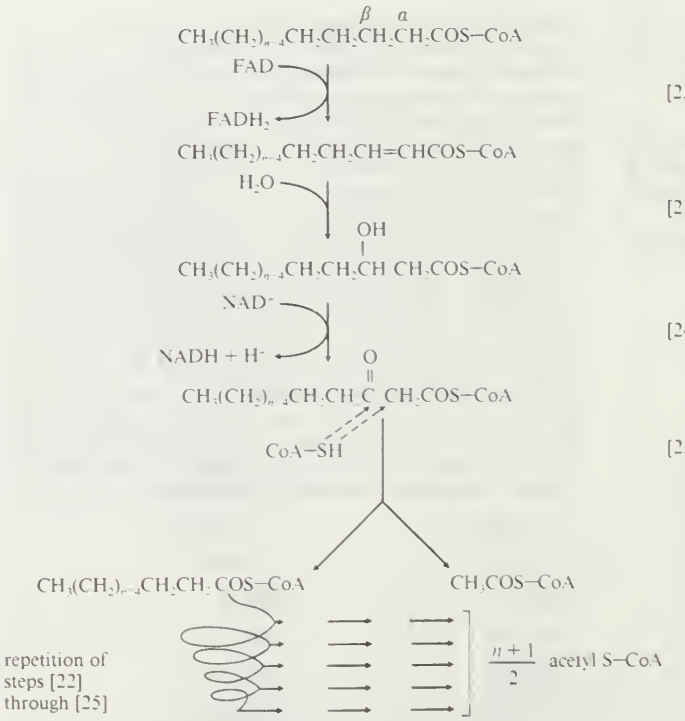


Figure 5: Fragmentation of acyl coenzyme A with an even number of carbon atoms (see text).

the carboxyl [—COOH] group of a fatty acid; the next closest is the β-, and so on to the end of the hydrocarbon chain.) The hydrogen atoms are accepted by the coenzyme FAD (flavin adenine dinucleotide), which is reduced to $FADH_2$. The product of step [22], α,β-unsaturated fatty acyl coenzyme A, is enzymatically hydrated [23]; *i.e.,* water is added across the double bond. The product, called a β-hydroxyacyl coenzyme A, can again be oxidized in an enzyme-catalyzed reaction [24]; the electrons removed are accepted by NAD^+. The product is called a β-ketoacyl coenzyme A.

The next enzymatic step [25] enables the energy invested in step [21] to be conserved. The β-ketoacyl coenzyme A that is the product of reaction [24] is split, not by water but by coenzyme A. The process, called thiolysis (as distinct from hydrolysis), yields the two-carbon fragment acetyl coenzyme A and a fatty acyl coenzyme A having two fewer carbon atoms than the molecule that underwent reaction [22]; otherwise the two are similar.

The shortened fatty acyl coenzyme A molecule now undergoes the sequence of reactions again, beginning with the dehydrogenation step [22], and another two-carbon fragment is removed as acetyl coenzyme A. With each passage through the process of fatty acid oxidation, the fatty acid loses a two-carbon fragment as acetyl coenzyme A and two pairs of hydrogen atoms to specific acceptors. The 16-carbon fatty acid, palmitic acid, for example, undergoes a total of seven such cycles, yielding eight molecules of acetyl coenzyme A and 14 pairs of hydrogen atoms, seven of which appear in the form of $FADH_2$ and seven in the form of $NADH + H^+$. The reduced coenzymes, $FADH_2$ and reduced NAD^+, are reoxidized when the electrons pass through the electron transport chain, with concomitant formation of ATP (see below *Biological energy transduction*). In anaerobes, organic molecules and not oxygen are electron acceptors; thus the yield of ATP is reduced. In all organisms, however, the acetyl coenzyme A formed from the breakdown of fatty acids joins that arising from the catabolism of carbohydrates (see below *The oxidation of pyruvate*) and many amino acids (see below *The catabolism of proteins*); Figure 2 shows the interrelationships.

Fatty acids with an odd number of carbon atoms are relatively rare in nature but may arise during microbial fermentations or through the oxidation of amino acids such as valine and isoleucine. They may be fragmented through repeated cycles of steps [22] to [25] until the final five-carbon acyl cocnzyme A is split into acetyl coenzyme A and propionyl coenzyme A, which has three carbon atoms. In many bacteria this propionyl coenzyme A can be transformed either to acetyl coenzyme A and carbon dioxide or to pyruvate. In other microorganisms and in animals propionyl coenzyme A has a different fate: carbon dioxide is added to propionyl coenzyme A in a reaction requiring ATP. The product, methylmalonyl coenzyme A, has four carbon atoms; the molecule undergoes a rearrangement, forming succinyl coenzyme A, which is an intermediate of the TCA cycle.

THE CATABOLISM OF PROTEINS

Role of amino acids

The amino acids derived from proteins function primarily as the precursors, or building blocks, for the cell's own proteins and (unlike lipids and carbohydrates) are not primarily a source of energy. Many microorganisms, on the other hand, can grow by using amino acids as the sole carbon and nitrogen source. Under these conditions these microorganisms derive from the amino acids all of their required energy and all of the precursors of the macromolecules that comprise the components of their cells. Moreover, it has been calculated that a man of average weight (70 kilograms, or 154 pounds) turns over about 0.4 kilogram of protein per day. About 0.1 kilogram is degraded and replaced by dietary amino acids; the remaining 0.3 kilogram is recycled as part of the dynamic state of cell constituents. The cells of plants contain and metabolize many amino acids in addition to the 20 or so that are normally found in proteins. A complete discussion of these special pathways is outside the scope of this article, however.

Before proteins can enter cells, the bonds linking adjacent amino acids (peptide bonds) must be hydrolyzed; this process releases the amino acids constituting the protein. The utilization of dietary proteins thus requires the operation of extracellular digestive enzymes; *i.e.,* enzymes outside the cell. Many microorganisms secrete such enzymes into the nutrient media in which they are growing; animals secrete them into the gut. The turnover of proteins within cells, on the other hand, requires the functioning of intracellular enzymes that catalyze the splitting of the peptide bonds linking adjacent amino acids; little is known about the mechanism involved.

Amino acids may be described by the general formula $RCH(NH_2)COOH$, or $RCH(NH_3^+)COO^-$, in which R represents a specific chemical moiety. The catabolic fate of amino acids involves (1) removal of nitrogen, (2) disposal of nitrogen, and (3) oxidation of the remaining carbon skeleton.

Removal of nitrogen. The removal of the amino group ($-NH_2$) generally constitutes the first stage in amino-acid catabolism. The amino group usually is initially transferred to the anion of one of three different α-keto acids (*i.e.,* of the general structure $RCOCOO^-$): pyruvate, which is an intermediate of carbohydrate fragmentation; or oxaloacetate or α-oxoglutarate, both intermediates of the TCA cycle. The products are alanine, aspartate, and glutamate (reactions [26a, b, and c]).

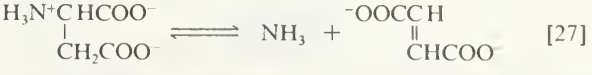
an amino acid — α-oxogutarate — α-keto acid anion — glutamate

Since the effect of these reactions is to produce n amino acids and n keto acids from n different amino acids and n different keto acids, no net reduction in the nitrogen content of the system has yet been achieved. The elimination of nitrogen occurs in a varicty of ways.

Elimination of nitrogen

In many microorganisms, ammonia (NH_3) can bc removed from aspartate via a reaction catalyzed by aspartasc [27]; the other product, fumarate, is an intermediate of the TCA cycle.



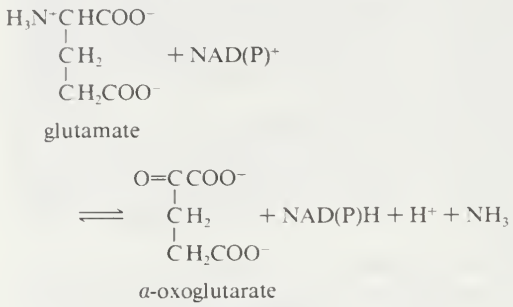
[27]

aspartate — fumarate

A quantitatively more important route is that catalyzed by glutamate dehydrogenasc, in which thc glutamate formcd in [26c] is oxidized to α-oxoglutarate, another TCA cyclc intcrmediate [28]. Eithcr $NADP^+$ or both $NADP^+$ and NAD^+ may servc as the hydrogen or electron acceptor, depending on thc organism; and somc organisms synthcsize two cnzymes, one of which prcfcrs $NADP^+$ and the

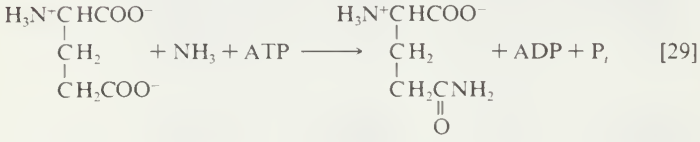
other NAD^+. In reaction [28], $NAD(P)^+$ is used to indicate that either NAD^+, $NADP^+$, or both may serve as the electron acceptor.

The occurrence of the transfer reactions [26] and either step [27] or, more importantly, step [28] allows the channeling of many amino acids into a common pathway by which nitrogen can be eliminated as ammonia.



glutamate — *α*-oxoglutarate [28]

Disposal of nitrogen. In animals that excrete ammonia as the main nitrogenous waste product (*e.g.*, some marine invertebrates, crustaceans), it is derived from nitrogen transfer reactions [26] and oxidation via glutamate dehydrogenase [28] as described above for microorganisms. Because ammonia is toxic to cells, however, it is detoxified as it forms. This process involves an enzyme-catalyzed reaction between ammonia and a molecule of glutamate; ATP provides the energy for the reaction, which results in the formation of glutamine, ADP, and inorganic phosphate [29]. This reaction [29] is catalyzed by glutamine synthetase, which is subject to a variety of metabolic controls. The glutamine thus formed gives up the amide nitrogen in the kidney tubules. As a result glutamate is formed once again, and ammonia is released into the urine.

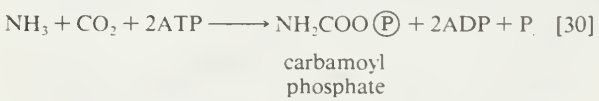


glutamate — glutamine [29]

Uric acid

In terrestrial reptiles and birds, uric acid rather than glutamate is the compound with which nitrogen combines to form a nontoxic substance for transfer to the kidney tubules. Uric acid is formed by a complex pathway that begins with ribose 5-phosphate and during which a so-called purine skeleton (see Figure 11) is formed; in the course of this process, nitrogen atoms from glutamine and the amino acids aspartic acid and glycine are incorporated into the skeleton. These nitrogen donors are derived from other amino acids via amino group transfer [26] and the reaction catalyzed by glutamine synthetase [29].

In most fishes, amphibians, and mammals, nitrogen is detoxified in the liver and excreted as urea, a readily soluble and harmless product. The sequence leading to the formation of urea, commonly called the urea cycle, is summarized as follows: Ammonia, formed from glutamate and NAD^+ in the liver mitochondria (reaction [28]), reacts with carbon dioxide and ATP to form carbamoyl phosphate, ADP, and inorganic phosphate, as shown in reaction [30].



carbamoyl phosphate [30]

Citrulline

The reaction is catalyzed by carbamoyl phosphate synthetase. The carbamoyl moiety of carbamoyl phosphate (NH_2CO-) is transferred to ornithine, an amino acid, in a reaction catalyzed by ornithine transcarbamoylase; the products are citrulline and inorganic phosphate [31]. Citrulline and aspartate formed from amino acids via step [26b] react to form argininosuccinate [32]; argininosuccinic acid synthetase catalyzes the reaction. Argininosuccinate splits into fumarate and arginine during a reaction

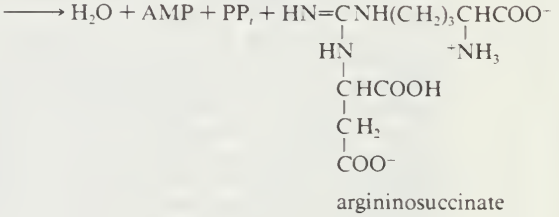
citrulline — aspartate [32]



argininosuccinate

arginine — fumarate

catalyzed by argininosuccinase [32a]. In the final step of the urea cycle, arginine, in a reaction catalyzed by arginase, is hydrolyzed [33]. Urea and ornithine are the products; ornithine thus is available to initiate another cycle beginning at step [31].

End products as intermediates

Oxidation of the carbon skeleton. As indicated in Figure 2, the carbon skeletons of amino acids (*i.e.*, the portion of the molecule remaining after the removal of nitrogen) are fragmented to form only a few end products; all of them are intermediates of either glycolysis or the TCA cycle. The number and complexity of the catabolic steps by which each amino acid arrives at its catabolic end point reflects the chemical complexity of that amino acid. Thus, in the case of alanine, only the amino group must be removed to yield pyruvate; the amino acid threonine, on the other hand, must be transformed successively to the amino acids glycine and serine before pyruvate is formed. The fragmentation of leucine to acetyl coenzyme A involves seven steps; that of tryptophan to the same end product requires 11. (A detailed discussion of the events

that enable each of the 20 commonly occurring amino acids to enter central metabolic pathways is beyond the scope of this article.)

The combustion of food materials

Although the pathways for fragmentation of food materials effect the conversion of a large variety of relatively complex starting materials into only a few simpler intermediates of central metabolic routes—mainly pyruvate, acetyl coenzyme A, and a few intermediates of the TCA cycle—their operation releases but a fraction of the energy contained in the materials. The reason is that, in the fermentation process, catabolic intermediates serve also as the terminal acceptors of the reducing equivalents (hydrogen atoms or electrons) that are removed during the oxidation of food; the end products thus may be at the same oxidation level and may contain equivalent numbers of carbon, hydrogen, and oxygen atoms, as the material that was catabolized by a fermentative route. The necessity for pyruvate, for example, to act as hydrogen acceptor in the fermentation of glucose to lactate (see reactions [1] through [11a]) results in the conservation of all the component atoms of the glucose molecule in the form of lactate. The consequent release of energy as ATP (in steps [7] and [10]) is thus small.

A more favourable situation arises if the reducing equivalents formed by oxidation of nutrients can be passed on to an inorganic acceptor such as oxygen. In this case, the products of fermentation need not act as "hydrogen sinks," in which the energy in the molecule is lost when they leave the cell; instead, the products of fermentation can be degraded further, during phase III of catabolism, and all the usable chemical energy of the nutrient can be transformed into ATP.

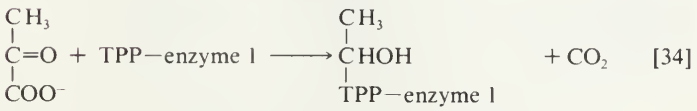
Importance of complete oxidation

This section describes the manner in which the products obtained by the fragmentation of nutrients are oxidized (*i.e.*, the manner in which hydrogen atoms or electrons are removed from them) and the manner in which these reducing equivalents react with oxygen, with concomitant formation of ATP.

THE OXIDATION OF MOLECULAR FRAGMENTS

The oxidation of pyruvate. The oxidation of pyruvate involves the concerted action of several enzymes and coenzymes collectively called the pyruvate dehydrogenase complex; *i.e.*, a multienzyme complex in which the substrates are passed consecutively from one enzyme to the next, and the product of the reaction catalyzed by the first enzyme immediately becomes the substrate for the second enzyme in the complex. The overall reaction is the formation of acetyl coenzyme A and carbon dioxide from pyruvate, with concomitant liberation of two reducing equivalents in the form of $NADH + H^+$. The individual reactions that result in the formation of these end products are as follows.

Pyruvate first reacts with the coenzyme of pyruvic acid decarboxylase (enzyme 1), thiamine pyrophosphate (TPP); in addition to carbon dioxide a hydroxyethyl–TPP–enzyme complex ("active acetaldehyde") is formed [34]. Thiamine is vitamin B_1; the biological role of TPP was first revealed by the inability of vitamin B_1-deficient animals to oxidize pyruvate.

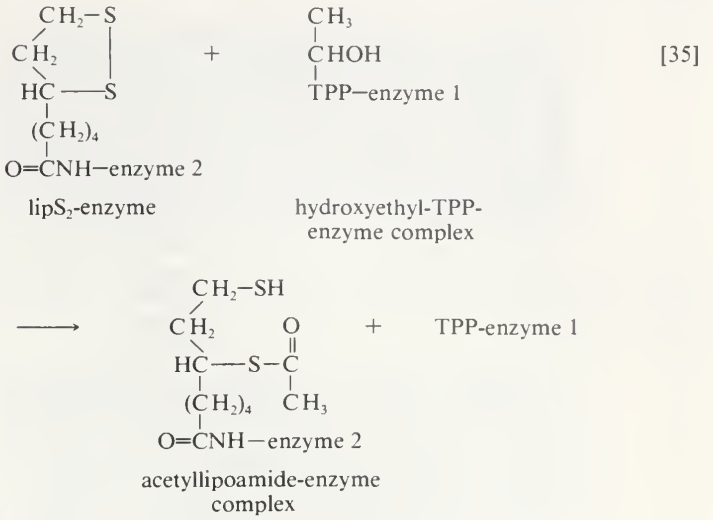


[34]

pyruvate — hydroxyethyl-TPP-enzyme complex

Enzyme 2

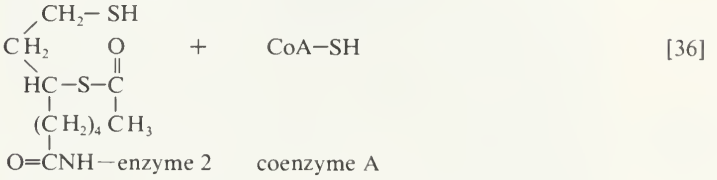
The hydroxyethyl moiety formed in [34] is immediately transferred to one of the two sulfur atoms (S) of the coenzyme (6,8-dithio-*n*-octanoate or $lipS_2$) of the second enzyme in the complex, dihydrolipoyl transacetylase (enzyme 2). The hydroxyethyl group attaches to $lipS_2$ at one of its sulfur atoms, as shown in [35]; the result is that coenzyme $lipS_2$ is reduced and the hydroxyethyl moiety is oxidized.



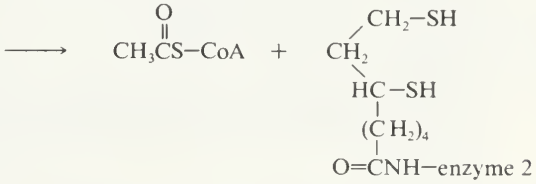
[35]

The acetyl group ($CH_3\overset{|}{C}{=}O$) then is transferred to the sulfhydryl (—SH) group of coenzyme A, thereby completing the oxidation of pyruvate (reaction [36]).

The coenzyme $lipS_2$ that accepted the hydroxyethyl moiety in step [35] of the sequence, now reduced, must be reoxidized before another molecule of pyruvate can be oxidized. The reoxidation of the coenzyme is achieved by the enzyme-catalyzed transfer of two reducing equivalents initially to the coenzyme flavin adenine dinucleotide (FAD) and thence to the NAD^+ that is the first carrier in the so-called electron transport chain. The passage of two such reducing equivalents from reduced NAD^+ to oxygen is accompanied by the formation of three molecules of ATP (see *Biological energy transduction*).



[36]



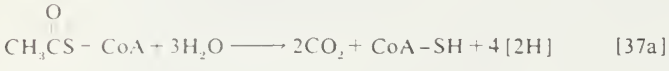
The overall reaction may be written as shown in [37], in which pyruvate reacts with coenzyme A in the presence of TPP and $lipS_2$ to form acetyl coenzyme A and carbon dioxide, and to liberate two hydrogen atoms (in the form of $NADH + H^+$) that can subsequently yield energy by the reduction of oxygen to water. The $lipS_2$ reduced during this process is reoxidized in the presence of the enzyme lipoyl dehydrogenase, with the concomitant reduction of NAD^+.

[37]

The tricarboxylic acid (TCA) cycle. Acetyl coenzyme A arises not only from the oxidation of pyruvate but also from that of fats (Figure 5) and many of the amino acids comprising proteins (Figure 2); the sequence of enzyme-

Acetyl coenzyme A

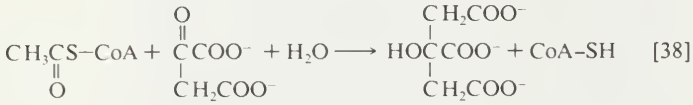
catalyzed steps that effects the total combustion of the acetyl moiety of the coenzyme represents the terminal oxidative pathway for virtually all food materials. The balance of the overall reaction of the TCA cycle [37a] is that three molecules of water react with acetyl coenzyme A to form carbon dioxide, coenzyme A, and reducing equivalents. The oxidation by oxygen of the reducing equivalents is accompanied by the conservation (as ATP) of most of the energy of the food ingested by aerobic organisms.



$$CH_3\overset{O}{\overset{\|}{C}}S\text{-}CoA + 3H_2O \longrightarrow 2CO_2 + CoA\text{-}SH + 4[2H] \qquad [37a]$$

acetyl coenzyme A — reducing equivalents

The relative complexity and number of chemical events that constitute the TCA cycle, and their location as components of spatially determined structures such as cell membranes in microorganisms and mitochondria in plants and higher animals, reflect the problems involved chemically in "dismembering" a compound having only two carbon atoms and releasing in a controlled and stepwise manner the reducing equivalents ultimately to be passed to oxygen. These problems have been overcome by the simple but effective device of initially combining the two-carbon compound with a four-carbon acceptor; it is much less difficult chemically to dismember and oxidize a compound having six carbon atoms.

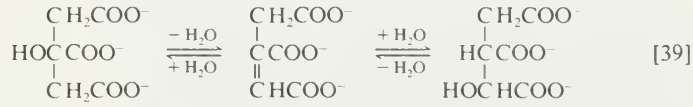


$$CH_3\overset{O}{\overset{\|}{C}}S\text{–}CoA + \underset{\displaystyle CH_2COO^-}{\overset{\displaystyle O}{\overset{\|}{C}}COO^-} + H_2O \longrightarrow \underset{\displaystyle CH_2COO^-}{\overset{\displaystyle CH_2COO^-}{\overset{|}{HOC}}COO^-} + CoA\text{–}SH \qquad [38]$$

acetyl coenzyme A — oxaloacetate — citrate

In the TCA cycle, acetyl coenzyme A initially reacts with oxaloacetate to yield citrate and to liberate coenzyme A. This reaction [38] is catalyzed by citrate synthase. (As mentioned above, many of the compounds in living cells that take part in metabolic pathways exist as charged moieties, or anions, and are named as such.) Citrate undergoes isomerization (*i.e.*, a rearrangement of certain atoms comprising the molecule) to form isocitrate [39]. The reaction involves first the removal of the elements of water from citrate to form *cis*-aconitate, and then the re-addition of water to *cis*-aconitate in such a way that isocitrate is formed. It is probable that all three reactants—citrate, *cis*-aconitate, and isocitrate—remain closely associated with aconitase, the enzyme that catalyzes the isomerization process, and that most of the *cis*-aconitate is not released from the enzyme surface but is immediately converted to isocitrate.

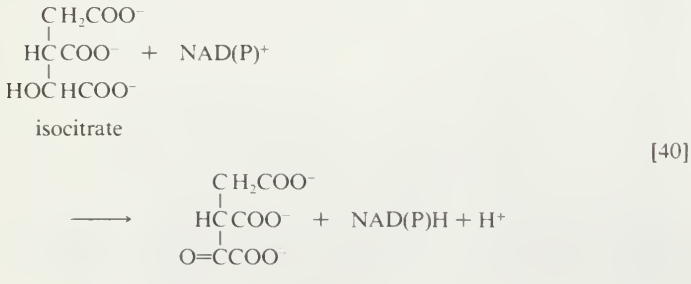
Isomerization



$$\underset{\displaystyle CH_2COO^-}{\overset{\displaystyle CH_2COO^-}{\overset{|}{HOC}}COO^-} \underset{+H_2O}{\overset{-H_2O}{\rightleftharpoons}} \underset{\displaystyle CHCOO^-}{\overset{\displaystyle CH_2COO^-}{\overset{|}{C}}COO^-} \underset{-H_2O}{\overset{+H_2O}{\rightleftharpoons}} \underset{\displaystyle HOCHCOO^-}{\overset{\displaystyle CH_2COO^-}{\overset{|}{HC}}COO^-} \qquad [39]$$

citrate — *cis*-aconitate — isocitrate

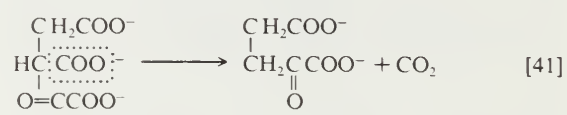
Isocitrate is oxidized—*i.e.*, hydrogen is removed—to form oxalosuccinate; the two hydrogen atoms are usually transferred to NAD^+, thus forming reduced NAD^+ [40]; in some microorganisms, and during the biosynthesis of glutamate in the cytoplasm of animal cells, however, the hydrogen atoms may also be accepted by $NADP^+$. Thus the enzyme controlling this reaction, isocitrate dehydrogenase, differs in specificity for the coenzymes; various forms occur not only in different organisms but even within the same cell. In [40] $NAD(P)^+$ indicates that either NAD^+ or $NADP^+$ can act as a hydrogen acceptor.



$$\underset{\displaystyle HOCHCOO^-}{\overset{\displaystyle CH_2COO^-}{\overset{|}{HC}}COO^-} + NAD(P)^+ \longrightarrow \underset{\displaystyle O{=}CCOO^-}{\overset{\displaystyle CH_2COO^-}{\overset{|}{HC}}COO^-} + NAD(P)H + H^+ \qquad [40]$$

isocitrate — oxalosuccinate

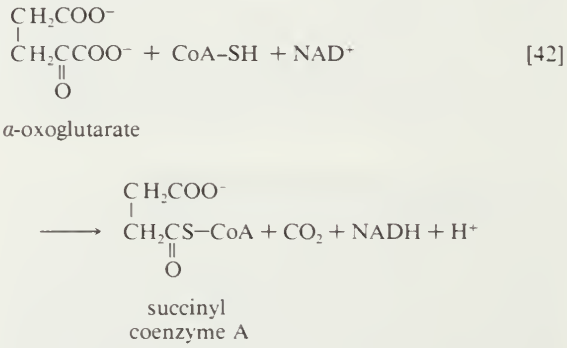
The position of the carboxylate ($-COO^-$) that is "sandwiched" in the middle of the oxalosuccinate molecule renders it very unstable; as a result, the carbon of this group is lost as carbon dioxide (note the dotted rectangle) in a reaction [41] that can occur spontaneously but may be further accelerated by an enzyme.



$$\underset{\displaystyle O{=}CCOO^-}{\overset{\displaystyle CH_2COO^-}{\overset{|}{HC}}COO^-} \longrightarrow \underset{\displaystyle O}{\overset{\displaystyle CH_2COO^-}{\overset{|}{CH_2C}}COO^-} + CO_2 \qquad [41]$$

oxalosuccinate — *α*-oxoglutarate

The five-carbon product of reaction [41], *α*-oxoglutarate, has chemical properties similar to pyruvate (free-acid forms of both are so-called *α*-oxoacids), and the chemical events involved in the oxidation of *α*-oxoglutarate are analogous to those already described for the oxidation of pyruvate (see reaction [37]). Reaction [42] is effected by a multienzyme complex; TPP, $lipS_2$ (6,8-dithio-*n*-octanoate), and coenzyme A are required as coenzymes. The products are carbon dioxide and succinyl coenzyme A. As was noted with reaction [37], this oxidation of *α*-oxoglutarate results in the reduction of $lipS_2$, which must be reoxidized. This is done by transfer of reducing equivalents to FAD and thence to NAD^+. The resultant $NADH + H^+$ is reoxidized by the passage of the electrons, ultimately, to oxygen, via the electron transport chain.



$$\underset{\displaystyle O}{\overset{\displaystyle CH_2COO^-}{\overset{|}{CH_2C}}COO^-} + CoA\text{–}SH + NAD^+ \qquad [42]$$

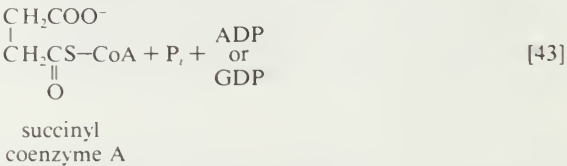
α-oxoglutarate

$$\longrightarrow \underset{\displaystyle O}{\overset{\displaystyle CH_2COO^-}{\overset{|}{CH_2C}}S\text{–}CoA} + CO_2 + NADH + H^+$$

succinyl coenzyme A

Unlike the acetyl coenzyme A produced from pyruvate in reaction [37], succinyl coenzyme A undergoes a phosphorolysis reaction—*i.e.*, transfer of the succinyl moiety from coenzyme A to inorganic phosphate. The succinyl phosphate thus formed is not released from the enzyme surface; an unstable, high-energy compound called an acid anhydride, it transfers a high-energy phosphate to ADP, directly or via guanosine diphosphate (GDP) [43].

Phosphorolysis



$$\underset{\displaystyle O}{\overset{\displaystyle CH_2COO^-}{\overset{|}{CH_2C}}S\text{–}CoA} + P_i + \underset{\text{or}}{\overset{\text{ADP}}{\text{GDP}}} \qquad [43]$$

succinyl coenzyme A

$$\longrightarrow \underset{\text{succinate}}{CH_2COO^-} + CoA\text{–}SH + \underset{\text{or}}{\overset{\text{ATP}}{\text{GTP}}}$$

If guanosine triphosphate (GTP) forms, ATP can readily arise from it in an exchange involving ADP [43a]:

$$GTP + ADP \rightleftharpoons ATP + GDP \qquad [43a]$$

The remainder of the reactions of the TCA cycle serve to regenerate the initial four-carbon acceptor of acetyl coenzyme A (oxaloacetate) from succinate, the process

requiring in effect the oxidation of a methylene group ($-CH_2-$) to a carbonyl group ($-CO-$), with concomitant release of $2 \times [2H]$ reducing equivalents. It is therefore similar to, and is effected in like manner to, the oxidation of fatty acids (steps [22–24]; see Figure 5). As is the case with fatty acids, hydrogen atoms or electrons are initially removed from the succinate formed in [43] and are accepted by FAD; the reaction, catalyzed by succinate dehydrogenase [44], results in the formation of fumarate and reduced FAD.

$$\begin{matrix} CH_2COO^- \\ | \\ CH_2COO^- \end{matrix} + FAD \longrightarrow \begin{matrix} {}^-OOCCH \\ \| \\ CHCOO^- \end{matrix} + FADH_2 \qquad [44]$$

succinate — fumarate

The elements of water are added across the double bond ($-CH{=}CH-$) of fumarate in a reaction catalyzed by fumarase [45]; this type of reaction also occurred in step [39] of the cycle. The product of reaction [45] is malate.

$$\begin{matrix} {}^-OOCCH \\ \| \\ CHCOO^- \end{matrix} + H_2O \rightleftharpoons \begin{matrix} HOCHCOO^- \\ | \\ CH_2COO^- \end{matrix} \qquad [45]$$

fumarate — malate

Malate can be oxidized to oxaloacetate by removal of two hydrogen atoms, which are accepted by NAD^+. This type of reaction, catalyzed by malate dehydrogenase in reaction [46], also occurred in step [40] of the cycle. The formation of oxaloacetate completes the TCA cycle, which can now begin again with the formation of citrate [38].

$$\begin{matrix} HOCHCOO^- \\ | \\ CH_2COO^- \end{matrix} + NAD^+ \longrightarrow \begin{matrix} O \\ \| \\ CCOO^- \\ | \\ CH_2COO^- \end{matrix} + NADH + H^+ \qquad [46]$$

malate — oxaloacetate

Energy conserved during the TCA cycle

The loss of the two molecules of carbon dioxide in steps [41] and [42] does not yield biologically useful energy. The substrate-linked formation of ATP accompanies step [43], in which one molecule of of ATP, is formed during each turn of the cycle. The hydrogen ions and electrons that result from steps [40], [42], [44], and [46] are passed down the chain of respiratory carriers to oxygen, with the concomitant formation of three molecules of ATP, per [2H], as $NADH + H^+$ (see below). Similarly, the oxidation of the reduced FAD formed in [44] results in the formation of two ATP. Each turn of the cycle thus leads to the production of a total of 12 ATP. It will be recalled that the anaerobic fragmentation of glucose to two molecules of pyruvate yielded two ATP; the aerobic oxidation via the TCA cycle of two molecules of pyruvate thus makes available to the cell at least 15 times more ATP per molecule of glucose catabolized than is produced anaerobically. If, in addition, the $2 \times [NADH + H^+]$ generated per glucose in reaction [6] are passed on to oxygen, a further six ATP are generated. The advantage to living organisms is to be able to respire rather than merely to ferment.

BIOLOGICAL ENERGY TRANSDUCTION

Adenosine triphosphate as the currency of energy exchange. When the terminal phosphate group is removed from ATP by hydrolysis, two negatively charged products are formed, ADP^{3-} and HPO_4^{2-} (a phosphate group) [47].

$$ATP^{4-} + H_2O \longrightarrow ADP^{3-} + HPO_4^{2-} + H^+ \qquad [47]$$

These products are electrically more stable than the parent molecule and do not readily recombine. The total free energy (G) of the products is much less than that of ATP; hence energy is liberated (*i.e.*, the reaction is exergonic).

Standard free energy

The amount of energy liberated under strictly defined conditions is called the standard free energy change ($\Delta G'$); this value for the hydrolysis of ATP is relatively high, at -8 kilocalories per mole. (One kilocalorie is the amount of heat required to raise the temperature of 1,000 grams of water one degree centigrade.) Conversely, the formation of ATP from ADP and inorganic phosphate (P_i) is an energy-requiring (*i.e.*, endergonic) reaction with a standard free energy change of $+8$ kilocalories per mole.

The hydrolysis of the remaining phosphate-to-phosphate bond of ADP is also accompanied by a liberation of free energy (the standard free energy change is -6.5 kilocalories per mole); AMP hydrolysis liberates less energy (the standard free energy change is -2.2 kilocalories per mole).

The free energy of hydrolysis of a compound thus is a measure of the difference in energy content between the starting substances (reactants) and the final substances (products). Adenosine triphosphate does not have the highest standard free energy of hydrolysis of all the naturally occurring phosphates but instead occupies a position at approximately the halfway point in a series of phosphate compounds with a wide range of standard free energies of hydrolysis. Compounds such as 1,3-diphosphoglycerate or phosphoenolpyruvate (PEP), which are above ATP on the scale (see Figure 6), have large negative $\Delta G'$ values on hydrolysis and are often called high-energy phosphates; they are said to exhibit a high phosphate group transfer potential because they have a tendency to lose their phosphate groups. Compounds such as glucose 6-phosphate or fructose 6-phosphate, which are below ATP on the scale because they have smaller negative $\Delta G'$ values on hydrolysis, have a tendency to hold on to their phosphate groups and thus act as low-energy phosphate acceptors.

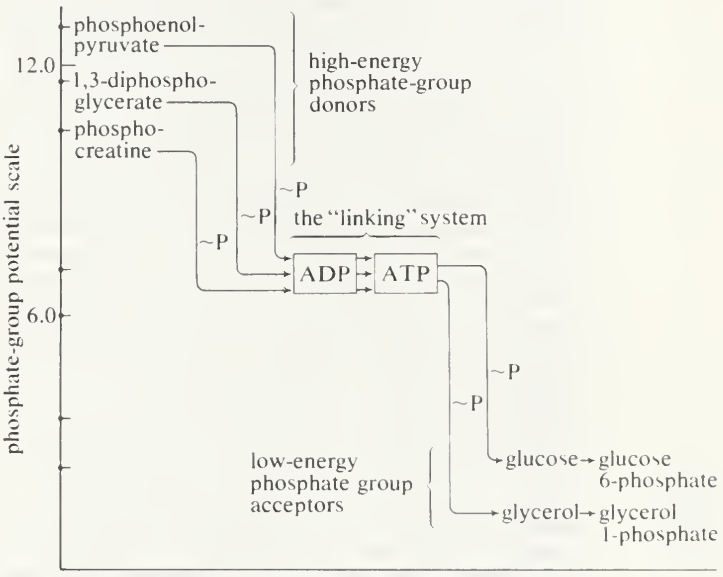


Figure 6: The transfer of phosphate groups from high-energy donors to low-energy acceptors by way of the ATP–ADP system (see text).

Both ATP and ADP act as intermediate carriers for the transfer of phosphate groups (which are more precisely called phosphoryl groups) and hence of energy, from compounds lying above ATP to those lying beneath it. Thus, in glycolysis, ADP acts as an acceptor of a phosphate group during the synthesis of ATP from PEP (see reaction [10]), and ATP functions as a donor of a phosphate group during the formation of fructose 1,6-diphosphate from fructose 6-phosphate (see reaction [3]).

The first step in glycolysis, the formation of glucose 6-phosphate (G6P), illustrates how an energetically unfavourable reaction may become feasible under intracellular conditions by coupling it to ATP.

ATP coupling

$$\text{glucose} + P_i \longrightarrow \text{G6P} \qquad \Delta G' = +3.3 \text{ kcal} \qquad [48]$$

$$ATP \longrightarrow ADP + P_i \qquad \Delta G' = -7.3 \text{ kcal} \qquad [48a]$$

$$\text{glucose} + ATP \longrightarrow \text{G6P} + ADP \qquad \Delta G' = -4 \text{ kcal} \qquad [48b]$$

Reaction [48] has a positive $\Delta G'$ value, indicating that the reaction tends to proceed in the reverse direction. It is therefore necessary to use the standard free energy generated by the breaking of the first phosphate bond in ATP (reaction [48a]), which is -7.3 kilocalories per mole, to move reaction [48] in the forward direction. Combining these reactions and their standard free energies gives reaction [48b] and a standard free energy value of -4 kilocalo-

ries per mole, indicating that the reaction will proceed in the forward direction. There are many intracellular reactions in which the formation of ADP or AMP from ATP provides energy for otherwise unfavourable biosyntheses. Some cellular reactions use equivalent phosphorylated analogues of ATP, for example, guanosine triphosphate (GTP) for protein synthesis.

The utilization of ATP to perform work

The function of ATP as a common intermediate of energy transfer during anabolism is further dealt with below (see *The biosynthesis of cell components*). In certain specialized cells or tissues the chemical energy of ATP is used to perform work other than the chemical work of anabolism; for example, mechanical work—such as muscular contraction, or the movement of contractile structures called cilia and flagella, which are responsible for the motility of many small organisms. The performance of osmotic work also requires ATP; *e.g.*, the transport of ions or metabolites through membranes against a concentration gradient, a process that is basically responsible for many physiological functions, including nerve conduction, the secretion of hydrochloric acid in the stomach, and the removal of water from the kidneys.

Energy conservation. The amount of ATP in a cell is limited, and it must be replaced continually to maintain repair and growth. This is achieved by using the energy liberated during the oxidative stages of catabolism to synthesize ATP from ADP and phosphate. The synthesis of ATP linked to catabolism occurs by two distinct mechanisms: substrate-level phosphorylation and oxidative, or respiratory-chain, phosphorylation. Oxidative phosphorylation is the major method of energy conservation under aerobic conditions in all nonphotosynthetic cells.

Substrate-level phosphorylation. In substrate-level phosphorylation a phosphoryl group is transferred from an energy-rich donor (*e.g.*, 1,3-diphosphoglycerate) to ADP to yield a molecule of ATP. This type of ATP synthesis (see reactions [7], [10], and [43]) does not require molecular oxygen (O_2), although it is frequently, but not always, preceded by an oxidation (*i.e.*, dehydrogenation) reaction. Substrate-level phosphorylation is the major method of energy conservation in oxygen-depleted tissues and during fermentative growth of microorganisms.

Oxidative, or respiratory-chain, phosphorylation. In oxidative phosphorylation the oxidation of catabolic intermediates by molecular oxygen occurs via a highly ordered series of substances that act as hydrogen and electron carriers. They constitute the electron transfer system, or respiratory chain. In most animals, plants, and fungi, the electron transfer system is fixed in the membranes of mitochondria; in bacteria (which have no mitochondria) this system is incorporated into the plasma membrane. Sufficient free energy is released to allow the synthesis of ATP by a process described below. First, however, it is necessary to consider the nature of the respiratory chain.

The electron transfer system

Four types of hydrogen or electron carriers are known to participate in the respiratory chain, in which they serve to transfer two reducing equivalents (2H) from reduced substrate (AH_2) to molecular oxygen (see reaction [49]); the products are the oxidized substrate (A) and water (H_2O).

$$AH_2 + \tfrac{1}{2}O_2 \longrightarrow A + H_2O \qquad [49]$$

The carriers are NAD^+ and, less frequently, $NADP^+$; the flavoproteins FAD and FMN (flavin mononucleotide); ubiquinone (or coenzyme Q); and several types of cytochromes. Each carrier has an oxidized and reduced form (*e.g.*, FAD and $FADH_2$, respectively), the two forms constituting an oxidation-reduction, or redox, couple. Within the respiratory chain each redox couple undergoes cyclic oxidation-reduction—*i.e.*, the oxidized component of the couple accepts reducing equivalents from either a substrate or a reduced carrier preceding it in the series and in turn donates these reducing equivalents to the next oxidized carrier in the sequence. Reducing equivalents are thus transferred from substrates to molecular oxygen by a number of sequential redox reactions.

Most oxidizable catabolic intermediates initially undergo a dehydrogenation reaction, during which a dehydrogenase enzyme transfers the equivalent of a hydride ion ($H^+ + 2e^-$, with e^- representing an electron) to its coenzyme, either NAD^+ or $NADP^+$. The reduced NAD^+ (or $NADP^+$) thus produced (usually written as $NADH + H^+$ or $NADPH + H^+$) diffuses to the membrane-bound respiratory chain to be oxidized by an enzyme known as NADH dehydrogenase; the enzyme has as its coenzyme FMN. There is no corresponding NADPH dehydrogenase in mammalian mitochondria; instead, the reducing equivalents of $NADPH + H^+$ are transferred to NAD^+ in a reaction catalyzed by a transhydrogenase enzyme, with the products being reduced $NADH + H^+$ and $NADP^+$. A few substrates (*e.g.*, acyl coenzyme A and succinate; see reactions [22] and [44]) bypass this reaction and instead undergo immediate dehydrogenation by specific membrane-bound dehydrogenase enzymes. During the reaction, the coenzyme FAD accepts two hydrogen atoms and two electrons ($2H + 2e^-$). The reduced flavoproteins (*i.e.*, $FMNH_2$ and $FADH_2$) donate their two hydrogen atoms to the lipid carrier ubiquinone, which is thus reduced.

The fourth type of carrier, the cytochromes, consists of hemoproteins—*i.e.*, proteins with a nonprotein component, or prosthetic group, called heme (or a derivative of heme), which is an iron-containing pigment molecule. The iron atom in the prosthetic group is able to carry one electron and oscillates between the oxidized, or ferric (Fe^{3+}), and the reduced, or ferrous (Fe^{2+}), forms. The five cytochromes present in the mammalian respiratory chain, designated cytochromes *b*, c_1, *c*, *a*, and a_3, act in sequence between ubiquinone and molecular oxygen. The terminal cytochrome of this sequence (a_3, also known as

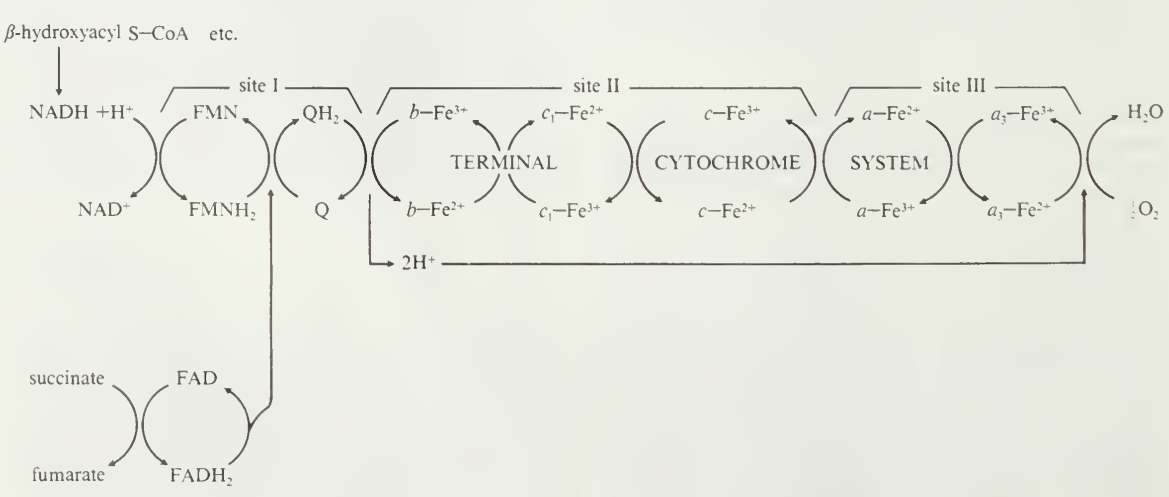

Figure 7: The respiratory chain (see text).

cytochrome oxidase) is able to donate electrons to oxygen rather than to another electron carrier; a_3 is also the site of action of two substances that inhibit the respiratory chain, potassium cyanide and carbon monoxide. Special Fe-S complexes play a role in the activity of NADH dehydrogenase and succinate dehydrogenase. The sequence of carriers, from substrates to oxygen, is shown schematically in Figure 7.

Sequence of carriers

In each redox couple the reduced form has a tendency to lose reducing equivalents (*i.e.*, to act as an electron or hydrogen donor); similarly, the oxidized form has a tendency to gain reducing equivalents (*i.e.*, to act as an electron or hydrogen acceptor). The oxidation-reduction characteristics of each couple can be determined experimentally under well-defined, standard conditions. The value thus obtained is the standard oxidation-reduction (redox) potential (E_0). Values for respiratory chain carriers range from $E_0 = -320$ millivolts (one millivolt = 0.001 volt) for NAD^+/reduced NAD^+ to $E_0 = +820$ millivolts for $^1/_2O_2/H_2O$; the values for intermediate carriers lie between. Reduced NAD^+ is the most electronegative carrier, oxygen the most electropositive acceptor. During respiration reducing equivalents undergo stepwise transfer from the reduced form of the most electronegative carrier (reduced NAD^+) to the oxidized form of the most electropositive couple (oxygen). Each step is accompanied by a decline in standard free energy ($\Delta G'$) proportional to the difference in the standard redox potentials (ΔE_0) of the two carriers involved.

Overall oxidation of reduced NAD^+ by oxygen ($\Delta E_0 = +1{,}140$ millivolts) is accompanied by the liberation of free energy ($\Delta G' = -52.4$ kilocalories per mole); in theory this energy is sufficient to allow the synthesis of six or seven molecules of ATP. In the cell, however, this synthesis of ATP, called oxidative phosphorylation, proceeds with an efficiency of about 46 percent; thus only three molecules of ATP are produced per atom of oxygen consumed—this being the so-called $P/2e^-$, P/O, or ADP/O ratio. The energy that is not conserved as ATP is lost as heat. The oxidation of succinate by molecular oxygen ($\Delta E_0 = +790$ millivolts), which is accompanied by a smaller liberation of free energy ($\Delta G' = -36.5$ kilocalories per mole), yields only two molecules of ATP per atom of oxygen consumed (P/O = 2).

Oxidative phosphorylation

In order to understand the mechanism by which the energy released during respiration is conserved as ATP, it is necessary to appreciate the structural features of mitochondria. These are organelles in animal and plant cells in which oxidative phosphorylation takes place. There are many mitochondria in animal tissues; for example, in heart and skeletal muscle, which require large amounts of energy for mechanical work, in the pancreas, where there is biosynthesis, and in the kidney, where the process of excretion begins. Mitochondria have an outer membrane, which allows the passage of most small molecules and ions, and a highly folded inner membrane (crista), which does not even allow the passage of small ions and so maintains a closed space within the cell. The electron-transferring molecules of the respiratory chain and the enzymes responsible for ATP synthesis are located in and on this inner membrane, while the space inside (matrix) contains the enzymes of the TCA cycle (reactions [34] to [46]; see also CELLS). The enzyme systems primarily responsible for the release and subsequent oxidation of reducing equivalents are thus closely related so that the reduced coenzymes formed during catabolism ($NADH + H^+$ and $FADH_2$) are available as substrates for respiration. The movement of most charged metabolites into the matrix space is mediated by special carrier proteins in the crista that catalyze exchange-diffusion (*i.e.*, a one-for-one exchange). The oxidative phosphorylation systems of bacteria are similar in principle but show a greater diversity in the composition of their respiratory carriers.

The mechanism of ATP synthesis appears to be as follows. During the transfer of hydrogen atoms from $FMNH_2$ or $FADH_2$ to oxygen (Figure 7), protons (H^+ ions) are pumped across the crista from the inside of the mitochondrion to the outside. Thus, respiration generates an electrical potential (and in mitochondria a small pH gradient) across the membrane corresponding to 200 to 300 millivolts, and the chemical energy in the substrate is converted into electrical energy. Attached to the crista is a complex enzyme (ATP synthetase) that binds ATP, ADP, and P_i. It has nine polypeptide chain subunits of five different kinds in a cluster and a unit of at least three more membrane proteins composing the attachment point of ADP and P_i. This complex forms a specific proton pore in the membrane. When ADP and P_i are bound to ATP synthetase, the excess of protons (H^+) that has formed outside of the mitochondria (an H^+ gradient) moves back into the mitochondrion through the enzyme complex. The energy released is used to convert ADP and P_i to ATP. In this process, electrical energy is converted to chemical energy, and it is the supply of ADP that limits the rate of this process. The precise mechanism by which the ATP synthetase complex converts the energy stored in the electrical H^+ gradient to the chemical bond energy in ATP is not well understood. The H^+ gradient may power other endergonic (energy-requiring) processes besides ATP synthesis, such as the movement of bacterial cells and the transport of carbon substrates or ions.

Photosynthesis generates ATP by a mechanism that is similar in principle, if not in detail. The organelles responsible are different from mitochondria, but they also form membrane-bounded closed sacs (thylakoids) often arranged in stacks (grana). Solar energy splits two molecules of H_2O into molecular oxygen (O_2), four protons (H^+), and four electrons.

Photosynthesis

This is the source of oxygen evolution, clearly visible as bubbles from underwater plants in bright sunshine. The process involves a chlorophyll molecule, P_{680}, that changes its redox potential from +820 millivolts (in which there is a tendency to accept electrons) to about −680 millivolts (in which there is a tendency to lose electrons) upon excitation with light and acquisition of electrons. The electrons are subsequently passed along a series of carriers (plastoquinone, cytochromes b and f, and plastocyanin), analogous to the mitochondrial respiratory chain. This process pumps protons across the membrane from the outside of the thylakoid membrane to the inside. Protons (H^+) do not move freely across the membrane although chloride ions (Cl^-) do, creating a pH gradient. An ATP synthetase enzyme similar to that of the mitochondria is present, but on the outside of the thylakoid membrane. Passage of protons (H^+) through it from inside to outside generates ATP.

Hence, a gradient of protons (H^+) across the membrane is the high-energy intermediate for forming ATP in plant photosynthesis and in the respiration of all cells capable of passing reducing equivalents (hydrogen atoms or electrons) to electron acceptors.

The biosynthesis of cell components

THE NATURE OF BIOSYNTHESIS

The stages of biosynthesis. The biosynthesis of cell components (anabolism) may be regarded as occurring in two main stages. In the first, intermediate compounds of the central routes of metabolism are diverted from further catabolism and are channeled into pathways that usually lead to the formation of the relatively small molecules that serve as the building blocks, or precursors, of macromolecules.

In the second stage of biosynthesis, the building blocks are combined to yield the macromolecules—proteins, nucleic acids, lipids, and polysaccharides—that make up the bulk of tissues and cellular components. In organisms with the appropriate genetic capability, for example, all of the amino acids can be synthesized from ammonia and intermediates of the main routes of carbohydrate fragmentation and oxidation. Such intermediates act also as precursors for the purines, the pyrimidines, and the pentose sugars that constitute DNA and for a number of types of RNA. The assembly of proteins necessitates the precise combination of specific amino acids in a highly ordered and controlled manner; this in turn involves the copying, or transcription, into RNA of specific parts of DNA (see below *The synthesis of macromolecules*). The

Requirements

first stage of biosynthesis thus requires the specificity normally required for the efficient functioning of sequences of enzyme-catalyzed reactions. The second stage also involves—directly for protein and nucleic acid synthesis, less directly for the synthesis of other macromolecules—the maintenance and expression of the biological information that specifies the identity of the cell, the tissue, and the organism.

Utilization of ATP. The two stages of biosynthesis—the formation of building blocks and their specific assembly into macromolecules—are energy-consuming processes and thus require ATP. Although the ATP is derived from catabolism, catabolism does not "drive" biosynthesis. As explained in the first section of this article, the occurrence of chemical reactions in the living cell is accompanied by a net decrease in free energy. Although biological growth and development result in the creation of ordered systems from less ordered ones and of complex systems from simpler ones, these events must occur at the expense of energy-yielding reactions. The overall coupled reactions are, on balance, still accompanied by a decrease in free energy and are thus essentially irreversible in the direction of biosynthesis. The total energy released from ATP, for example, is usually much greater than is needed for a particular biosynthetic step; thus, many of the reactions involved in biosynthesis release inorganic pyrophosphate (PP_i) rather than phosphate (P_i) from ATP, and hence yield AMP rather than ADP. Since inorganic pyrophosphate readily undergoes virtually irreversible hydrolysis to two equivalents of inorganic phosphate (see [21a]), the creation of a new bond in the product of synthesis may be accompanied by the breaking of two high-energy bonds of ATP—although, in theory, one might have sufficed.

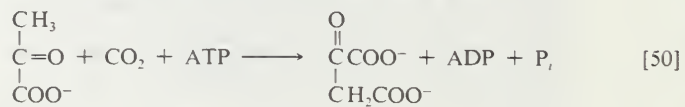
The efficient utilization for anabolic processes of ATP and some intermediate compound formed during a catabolic reaction requires the cell to have simultaneously a milieu favourable for both ATP generation and consumption. Catabolism occurs readily only if sufficient ADP is available; hence, the concentration of ATP is low. On the other hand, biosynthesis requires a high level of ATP and consequently low levels of ADP and AMP. Suitable conditions for the simultaneous function of both processes are met in two ways. Biosynthetic reactions often take place in compartments within the cell different from those in which catabolism occurs; there is thus a physical separation of energy-requiring and energy-yielding processes. Furthermore, biosynthetic reactions are regulated independently of the mechanisms by which catabolism is controlled. Such independent control is made possible by the fact that catabolic and anabolic pathways are not identical; the pacemaker, or key, enzyme that controls the overall rate of a catabolic route usually does not play any role in the biosynthetic pathway of a compound. Similarly, the pacemaker enzymes of biosynthesis are not involved in catabolism. As discussed below (see *Regulation of metabolism: Fine control*), catabolic pathways are often regulated by the relative amounts of ATP, ADP, and AMP in the cellular compartment in which the pacemaker enzymes are located; in general, ATP inhibits and ADP (or AMP) stimulates such enzymes. In contrast, many biosynthetic routes are regulated by the concentration of the end products of particular anabolic processes, so that the cell synthesizes only as much of these building blocks as it needs.

Regulation

THE SUPPLY OF BIOSYNTHETIC PRECURSORS

When higher animals consume a mixed diet, sufficient quantities of compounds for both biosynthesis and energy supply are available. Carbohydrates yield intermediates of glycolysis and of the phosphogluconate pathway, which in turn yield acetyl coenzyme A (see Figure 4); lipids yield glycolytic intermediates and acetyl coenzyme A (see Figure 2); and many amino acids form intermediates of both the TCA cycle and glycolysis. Any intermediate withdrawn for biosynthesis can thus be readily replenished by the catabolism of further nutrients. This situation does not always hold, however. Microorganisms in particular can derive all of their carbon and energy requirements by utilizing a single carbon source. The sole carbon source may be a substance such as a carbohydrate or a fatty acid, or an intermediate of the TCA cycle (or a substance readily converted to one). In both cases, reactions ancillary to those discussed thus far must occur before the carbon source can be utilized.

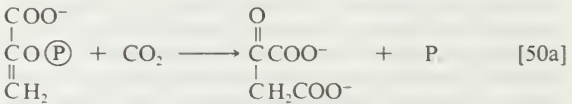
Anaplerotic routes. Although the catabolism of carbohydrates can occur via a variety of routes (see Figure 4), all give rise to pyruvate. During the catabolism of pyruvate, one carbon atom is lost as carbon dioxide and the remaining two form acetyl coenzyme A [37]; these two are involved in the TCA cycle ([41] and [42]). Because the TCA cycle is initiated by the condensation of acetyl coenzyme A with oxaloacetate, which is regenerated in each turn of the cycle, the removal of any intermediate from the cycle would cause the cycle to stop. Yet, as also indicated in Figure 4, various essential cell components are derived from α-oxoglutarate, succinyl coenzyme A, and oxaloacetate, so that these compounds are, in fact, removed from the cycle. Microbial growth with a carbohydrate as the sole carbon source is thus possible only if a cellular process occurs that effects the net formation of some TCA cycle intermediate from an intermediate of carbohydrate catabolism. Such a process, which replenishes the TCA cycle, has been described as an anaplerotic reaction.



pyruvate oxaloacetate [50]

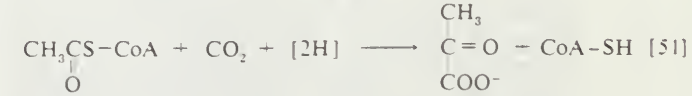
The anaplerotic function may be carried out by either of two enzymes that catalyze the fixation of carbon dioxide onto a three-carbon compound, either pyruvate [50] or phosphoenolpyruvate (PEP, [50a]) to form oxaloacetate, which has four carbon atoms. Both reactions require energy. In [50] it is supplied by the cleavage of ATP to ADP and inorganic phosphate (P_i); in [50a] it is supplied by the release of the high-energy phosphate of PEP as inorganic phosphate. Pyruvate serves as a carbon dioxide acceptor not only in many bacteria and fungi but also in the livers and kidneys of higher organisms, including man; PEP serves as the carbon dioxide acceptor in many bacteria, such as those that inhabit the gut.

Carbon dioxide acceptors



PEP oxaloacetate [50a]

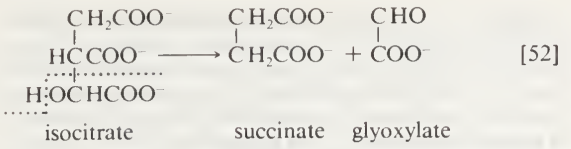
Unlike higher organisms, many bacteria and fungi can grow on acetate or compounds such as ethanol or a fatty acid that can be catabolized to acetyl coenzyme A. Under these conditions, the net formation of TCA cycle intermediates proceeds in one of two ways. In obligate anaerobic bacteria, pyruvate can be formed from acetyl coenzyme A and carbon dioxide [51]; reducing equivalents [2H] are necessary for the reaction. The pyruvate so formed can then react via either step [50] or [50a].



acetyl coenzyme A pyruvate [51]

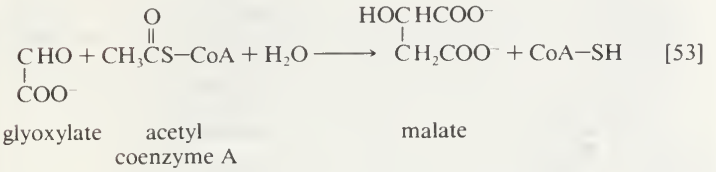
Reaction [51] does not occur in facultative anaerobic organisms or in strict aerobes, however. Instead, in these organisms two molecules of acetyl coenzyme A give rise to the net synthesis of a four-carbon intermediate of the TCA cycle via a route known as the glyoxylate cycle. In this route (Figure 8), the steps of the TCA cycle that lead to the loss of carbon dioxide (see [40], [41], and [42]) are bypassed. Instead of being oxidized to oxalosuccinate, as occurs in [40], isocitrate is split by isocitrate lyase [52] in a reaction similar to that of reactions [4] and [15] of carbohydrate fragmentation. The dotted line in [52] indicates the way in which isocitrate is split. The products are

The glyoxylate cycle



isocitrate succinate glyoxylate [52]

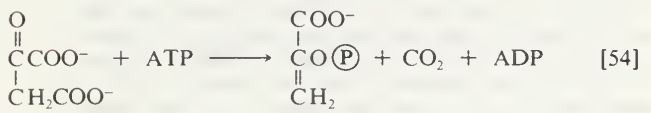
succinate and glyoxylate. Glyoxylate, like oxaloacetate, is the anion of an α-oxoacid and thus can condense, in a reaction catalyzed by malate synthase, with acetyl coenzyme A; the products of this reaction are coenzyme A and malate [53].



glyoxylate acetyl coenzyme A malate [53]

In conjunction with the reactions of the TCA cycle that effect the re-formation of isocitrate from malate (steps [46], [38], and [39]), steps [52] and [53] lead to the net production of a four-carbon compound (malate) from two two-carbon units (glyoxylate and acetyl coenzyme A). The sequence thus complements the TCA cycle, enabling the cycle to fulfill the dual roles of providing both energy and biosynthetic building blocks when the sole carbon source is a two-carbon compound such as acetate.

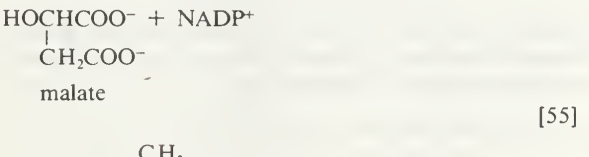
Growth of microorganisms on TCA cycle intermediates. Most aerobic microorganisms grow readily on substances such as succinate or malate as their sole source of carbon. Under these circumstances, the formation of the intermediates of carbohydrate metabolism requires an enzymatic step ancillary to the central pathways. In most cases this step is catalyzed by phosphoenolpyruvate (PEP) carboxykinase [54]. Oxaloacetate is decarboxylated (*i.e.*, carbon dioxide is removed) during this energy-requiring reaction. The energy may be supplied by ATP or a similar substance (*e.g.*, GTP) that can readily be derived from it via a reaction of the type shown in [43a]. The products are PEP, carbon dioxide, and ADP.



oxaloacetate PEP [54]

The malic enzyme

Another reaction that can yield an intermediate of carbohydrate catabolism is catalyzed by the so-called malic enzyme; in this reaction, malate is decarboxylated to pyruvate, with concomitant reduction of $NADP^+$ [55]. The primary role of malic enzyme, however, may be to generate reduced $NADP^+$ for biosynthesis rather than to form an intermediate of carbohydrate catabolism.



malate pyruvate [55]

THE SYNTHESIS OF BUILDING BLOCKS

Gluconeogenesis. The formation of sugars from noncarbohydrate precursors, gluconeogenesis, is of major importance in all living organisms. In the light, photosynthetic plants and microorganisms incorporate, or fix, carbon dioxide onto a five-carbon sugar and, via a sequence of transfer reactions, re-form the same sugar while also effecting the net synthesis of the glycolytic intermediate, 3-phosphoglycerate (see PHOTOSYNTHESIS). Phosphoglycerate is the precursor of starch, cell-wall carbohydrates,

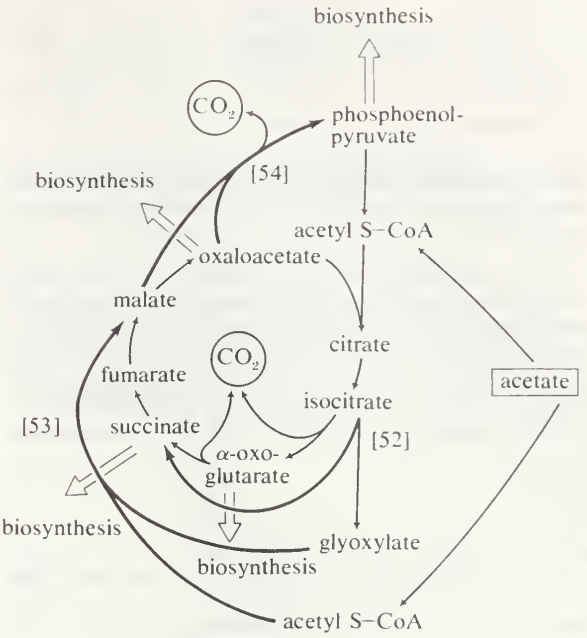


Figure 8: The glyoxylate cycle. Numbers refer to reactions described in text.

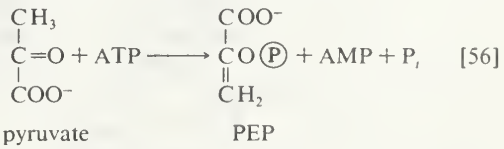
and other plant polysaccharides. A situation similar in principle applies to the growth of microorganisms on precursors of acetyl coenzyme A (Figure 8) or on intermediates of the TCA cycle—that is, a large variety of cell components are derived from carbohydrates that, in turn, are synthesized from these noncarbohydrate precursors. Higher organisms also readily convert glucogenic amino acids (*i.e.*, those that do not yield acetyl coenzyme A as a catabolic product) into TCA cycle intermediates, which are then converted into glucose. The amounts of glucose thus transformed depend on the needs of the organism for protein synthesis and on the availability of fuels other than glucose. The synthesis of blood glucose from lactate, which occurs largely in liver, is a particularly active process during recovery from intense muscular activity.

Most of the steps in the pathway for the biosynthesis of glucose from pyruvate are catalyzed by the enzymes of glycolysis; the direction of the reactions is reversed. Three virtually irreversible steps in glucose catabolism (see [10], [3], and [1]) that cannot be utilized in gluconeogenesis, however, are bypassed by alternative reactions that tend to proceed in the direction of glucose synthesis (Figure 9).

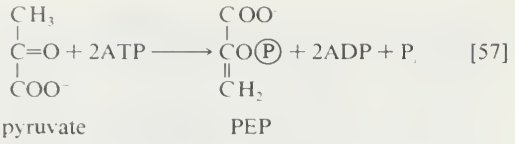
The first alternative reaction is the conversion of pyruvate to PEP. Three mechanisms for overcoming the energy barrier associated with the direct reversal of the pyruvate kinase reaction [10] are known. In some bacteria, PEP is formed from pyruvate by the utilization of two of the high-energy bonds of ATP; the products include, in addition to PEP, AMP and inorganic phosphate [56]. A variant of this reaction occurs in some bacteria, in which ATP and inorganic phosphate are reactants and AMP and inorganic pyrophosphate are products; as mentioned above, inorganic pyrophosphate is likely to be hydrolyzed to two equivalents of inorganic phosphate, so that the net balance of the reaction is identical with [56].



pyruvate PEP [56]

Formation of PEP from pyruvate

In other organisms, including many microorganisms, birds, and mammals, the formation of PEP from pyruvate is effected by the sum of reactions [50] and [54], each of which consumes one ATP; the overall balance is shown in [57], in which two molecules of ATP react with pyruvate to form PEP, ADP, and inorganic phosphate. The enzyme adenylate kinase catalyzes the interconversion of the various adenine nucleotides, as shown in [58].



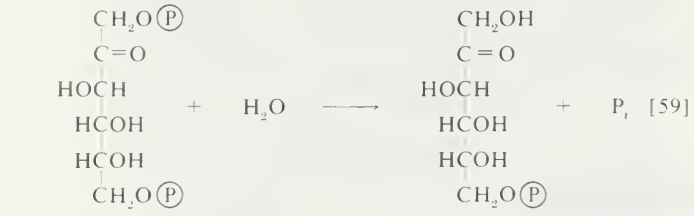
[57]

The combination of steps [57] and [58] yields the same energy balance as does the direct conversion of pyruvate to PEP [56].

$$2ADP \rightleftharpoons ATP + AMP \qquad [58]$$

Phosphofructokinase

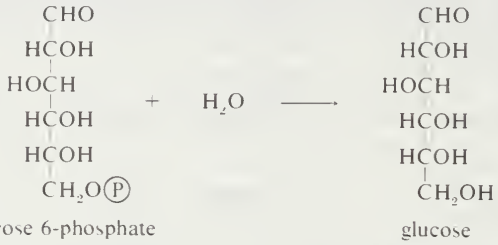
The second step of glycolysis bypassed in gluconeogenesis is that catalyzed by phosphofructokinase [3]. Instead, the fructose 1,6-diphosphate synthesized from dihydroxyacetonephosphate and glyceraldehyde 3-phosphate in the reaction catalyzed by aldolase is hydrolyzed, with the loss of the phosphate group linked to the first carbon atom.



[59]

fructose 1,6-diphosphate — fructose 6-phosphate

The enzyme fructose diphosphatase catalyzes the reaction [59], in which the products are fructose 6-phosphate and inorganic phosphate. The fructose 6-phosphate thus formed is a precursor of mucopolysaccharides (polysaccharides with nitrogen-containing components). In addition, its conversion to glucose 6-phosphate provides the starting material for the formation of storage polysaccharides such as starch and glycogen, of monosaccharides other than glucose, of disaccharides (carbohydrates with two sugar components), and of some structural polysaccharides (*e.g.*, cellulose). The maintenance of the glucose content of vertebrate blood requires glucose 6-phosphate to be converted to glucose. This process occurs in the kidney, in the lining of the intestine, and most importantly in the liver. The reaction does not occur by reversal of the hexokinase or glucokinase reactions that effect the formation of glucose 6-phosphate from glucose and ATP [1]; rather, glucose 6-phosphate is hydrolyzed in a reaction catalyzed by glucose 6-phosphatase, and the phosphate is released as inorganic phosphate [60].



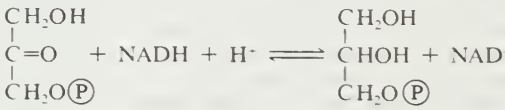
[60]

glucose 6-phosphate — glucose

Building blocks of lipids

Lipid components. The component building blocks of the lipids found in storage fats, in lipoproteins (combinations of lipid and protein), and in the membranes of cells and organelles are glycerol, the fatty acids, and a number of other compounds (*e.g.*, serine, inositol).

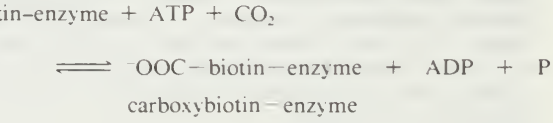
Glycerol. Glycerol is readily derived from dihydroxyacetone phosphate, an intermediate of glycolysis (see [4]). In a reaction catalyzed by glycerol 1-phosphate dehydrogenase [61], dihydroxyacetone phosphate is reduced to glycerol 1-phosphate; reduced NAD^+ provides the reducing equivalents for the reaction and is oxidized. This compound reacts further (see below *Other components*).



[61]

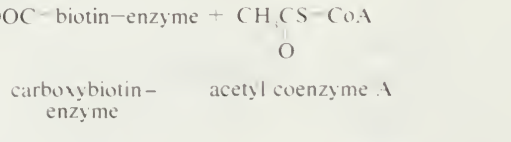
dihydroxyacetone phosphate — glycerol 1-phosphate

Fatty acids. Although all the carbon atoms of the fatty acids found in lipids are derived from the acetyl coenzyme A produced by the catabolism of carbohydrates and fatty acids (Figure 2), the molecule first undergoes a carboxylation, forming malonyl coenzyme A, before participating in fatty acid synthesis. The carboxylation reaction is catalyzed by acetyl CoA carboxylase, an enzyme whose prosthetic group is the vitamin biotin. The biotin–enzyme first undergoes a reaction that results in the attachment of carbon dioxide to biotin; ATP is required and forms ADP and inorganic phosphate [62a]. The complex product,



[62a]

called carboxybiotin–enzyme, releases the carboxy moiety to acetyl coenzyme A, forming malonyl coenzyme A and restoring the biotin–enzyme [62b].



[62b]

The overall reaction [62] catalyzed by acetyl coenzyme A carboxylase thus involves the expenditure of one molecule of ATP for the formation of each molecule of malonyl coenzyme A from acetyl coenzyme A and carbon dioxide.

Malonyl coenzyme A and a molecule of acetyl coenzyme A react (in bacteria) with the sulfhydryl group of

a relatively small molecule known as acyl-carrier protein (ACP–SH); in higher organisms ACP–SH is part of a multienzyme complex called fatty acid synthetase. ACP–SH is involved in all of the reactions leading to the synthesis of a fatty acid such as palmitic acid from acetyl coenzyme A and malonyl coenzyme A. The products of [63a] and [63b] are acetyl-S-ACP, malonyl-S-ACP, and coenzyme A. The enzymes catalyzing [63a] and [63b] are known as acetyl transacylase and malonyl transacylase, respectively. Acetyl-ACP and malonyl-ACP react in a reaction catalyzed by β-ketoacyl-ACP synthetase so that the acetyl moiety (CH_3CO-) is transferred to the malonyl moiety ($^-OOCH_2CO-$). Simultaneously, the carbon dioxide fixed in step [62] is lost, leaving as a product a four-carbon moiety attached to ACP and called acetoacetyl-S-ACP [64].

It should be noted that the carbon atoms of acetyl-S-ACP occur at the end of acetoacetyl-S-ACP (see carbon atoms numbered 4 and 3 in [64]) and that carbon dioxide plays an essentially catalytic role; the decarboxylation of the malonyl-S-ACP [64] provides a strong thermodynamic pull toward fatty acid synthesis.

Fatty acid synthesis and breakdown

The analogy between reaction [64] of fatty acid synthesis and the cleavage reaction [25] of fatty acid catabolism is apparent in the other reactions of fatty acid synthesis. The acetoacetyl-S-ACP, for example, undergoes reduction to β-hydroxybutyryl-S-ACP [65]; the reaction is catalyzed by β-ketoacyl-ACP reductase. Reduced $NADP^+$ is the electron donor, however, and not reduced NAD^+ (which would participate in the reversal of reaction [24]). $NADP^+$ is thus a product in [65]. In [66] β-hydroxybutyryl-S-ACP is dehydrated (*i.e.*, one molecule of water is removed), in a reaction catalyzed by enoyl-ACP-hydrase, and then undergoes a second reduction [67], in which reduced $NADP^+$

$$\rightleftharpoons CH_3\underset{OH}{CH}CH_2\overset{\overset{O}{\|}}{C}S{-}ACP + NADP^+$$

β-hydroxybutyryl-S–ACP

again acts as the electron donor. The products of [66] are crotonyl-S-ACP and water. The products of [67], which is catalyzed by crotonyl-ACP reductase, are butyryl-S-ACP and $NADP^+$.

$$CH_3\underset{OH}{CH}CH_2\overset{\overset{O}{\|}}{C}S{-}ACP \rightleftharpoons CH_3CH{=}CH\overset{\overset{O}{\|}}{C}S{-}ACP + H_2O \qquad [66]$$

hydroxybutyryl-S–ACP — crotonyl-S–ACP

The formation of butyryl-S-ACP [67] completes the first of several cycles, in each of which one molecule of malonyl coenzyme A enters via reactions [62] and [63b]. In the cycle following the one ending with [67], the butyryl moiety is transferred to malonyl-S-ACP, and a molecule of carbon dioxide is again lost; a six-carbon compound results. In subsequent cycles, each of which adds two carbon atoms to the molecule via reaction [64], successively longer β-oxoacyl-S-ACP derivatives are produced.

$$CH_3CH{=}CH\overset{\overset{O}{\|}}{C}S{-}ACP + NADPH + H^+ \qquad [67]$$

crotonyl-S–ACP

$$\rightleftharpoons CH_3CH_2CH_2\overset{\overset{O}{\|}}{C}S{-}ACP + NADP^+$$

butyryl-S–ACP

Ultimately, a molecule with 16 carbon atoms, palmityl-S-ACP, is formed. In most organisms a deacylase catalyzes the release of free palmitic acid; in a few, synthesis continues, and an acid with 18 carbon atoms is formed. The fatty acids can then react with coenzyme A (compare reaction [21]) to form fatty acyl coenzyme A, which can condense with the glycerol 1-phosphate formed in step [61]; the product is a phosphatidic acid. The overall formation of each molecule of palmitic acid from acetyl coenzyme A—via step [62] and repeated cycles of steps [63] through [67]—requires the investment of seven molecules of ATP and 14 of reduced $NADP^+$ (see [68]). The process is thus an energy-requiring one (endergonic) and represents a major way by which the reducing power generated in NADP-linked dehydrogenation reactions of carbohydrate catabolism is utilized (see above *The phosphogluconate pathway*).

Other components. The major lipids that serve as components of membranes, called phospholipids, as well as lipoproteins, contain, in addition to two molecules of fatty acid, one molecule of a variety of different compounds. The precursors of these compounds include serine, inositol, and glycerol 1-phosphate. They are derived from

Phospholipids

intermediates of the central metabolic pathways (*e.g.*, Figure 10; reaction [61]).

Amino acids. Organisms differ considerably in their ability to synthesize amino acids from the intermediates of central metabolic pathways. Most vertebrates can form only the chemically most simple amino acids; the others must be supplied in the diet. Man, for example, synthesizes about 10 of the 20 commonly encountered amino acids; these are termed nonessential amino acids. The essential amino acids must be supplied in food.

Higher plants are more versatile than animals; they can make all of the amino acids required for protein synthesis, with either ammonia (NH_3) or nitrate (NO_3^-) as the nitrogen source. Some bacteria, and leguminous plants (*e.g.*, peas) that harbour such bacteria in their root nodules, are able to utilize nitrogen from the air to form ammonia and use the latter for amino-acid synthesis.

Bacteria differ widely in their ability to synthesize amino acids. Some species, such as *Escherichia coli*, which can grow in media supplied with only a single carbon source and ammonium salts, can make all of their amino acids from these starting materials. Other bacteria may require as many as 16 different amino acids.

Amino-acid synthesis

Each of the 20 common amino acids is synthesized by a different pathway, the complexity of which reflects the chemical complexity of the amino acid formed. As with other compounds, the pathway for the synthesis of an amino acid is for the most part different from that by which it is catabolized. A detailed discussion of the pathway by which each amino acid is formed is beyond the scope of this article, but two salient features of amino-acid biosynthesis should be mentioned.

First, ammonia is incorporated into the intermediates of metabolic pathways mainly via the glutamate dehydrogenase reaction [28], which proceeds from right to left in biosynthetic reactions. Similarly, the transaminase enzymes (reactions [26a, b, and c]) enable the amino group (NH_2-) to be transferred to other amino acids.

Second, a group of several amino acids may be synthesized from one amino acid, which acts as a "parent" of an amino-acid "family." The families are also interrelated in several instances. Figure 10 shows, for bacteria that can synthesize 20 amino acids, the way in which they are derived from intermediates of pathways already considered. Alpha-oxoglutarate and oxaloacetate are intermediates of the TCA cycle; pyruvate, 3-phosphoglycerate, and PEP are intermediates of glycolysis; and ribose 5-phosphate and erythrose 4-phosphate are formed in the phosphogluconate pathway.

Mononucleotides. Most organisms can synthesize the purine and pyrimidine nucleotides that serve as the building blocks of RNA (containing nucleotides in which the pentose sugar is ribose, called ribonucleotides) and DNA (containing nucleotides in which the pentose sugar is deoxyribose, called deoxyribonucleotides) as well as the agents of energy exchange.

Purine ribonucleotides. The purine ribonucleotides (AMP and GMP) are derived from ribose 5-phosphate. The overall sequence that leads to the parent purine ribonucleotide, which is inosinic acid, involves 10 enzymatic steps.

Figure 11 is an outline of the manner in which inosinic acid is synthesized. Inosinic acid can be converted to AMP and GMP; these in turn yield the triphosphates (*i.e.*, ATP and GTP) via reactions catalyzed by adenylate kinase [69] and nucleoside diphosphate kinase (see reaction [43a]).

Inosinic acid

$$GMP + ATP \rightleftharpoons GDP + ADP \qquad [69]$$

Pyrimidine ribonucleotides. The biosynthetic pathway for the pyrimidine nucleotides is somewhat simpler than that for the purine nucleotides. Aspartate (derived from

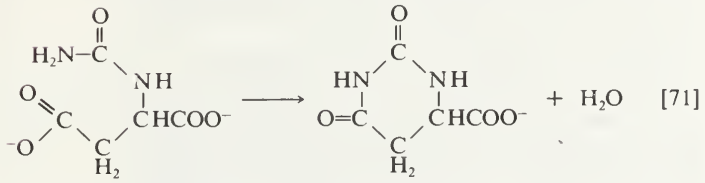
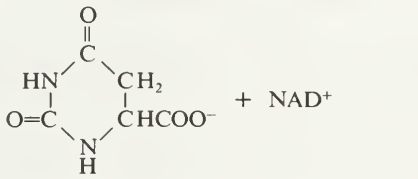
the TCA cycle intermediate, oxaloacetate) and carbamoyl phosphate (derived from carbon dioxide, ATP, and ammonia via reaction [30]) condense to form *N*-carbamoylaspartate [70], which loses water [71] in a reaction catalyzed by dihydroorotase; the product, dihydroorotate,

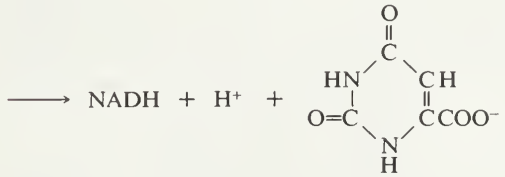


N-carbamoylaspartate dihydroorotate [71]

Orotate is then oxidized to orotate in a reaction catalyzed by dihydroorotic acid dehydrogenase, in which NAD^+ is reduced [72].



dihydroorotate [72]



orotate

The orotate accepts a pentose phosphate moiety [73] from 5-phosphoribose 1-pyrophosphate (PRPP); PRPP, which is formed from ribose 5-phosphate and ATP, also initiates the pathways for biosynthesis of purine nucleotides (Figure 11) and of histidine (Figure 10). The product loses carbon dioxide to yield the parent pyrimidine nucleotide, uridylic acid (UMP; see [73]).

Analogous to the phosphorylation of purine nucleotides (steps [69] and [43a]) is the phosphorylation of UMP to UDP and thence to UTP by interaction with two molecules of ATP. Uridine triphosphate (UTP) can be converted to the other pyrimidine building block of RNA, cytidine triphosphate (CTP). In bacteria, the nitrogen for this reaction [74] is derived from ammonia; in higher animals, glutamine is the nitrogen donor.

Deoxyribonucleotides. The building blocks for the synthesis of DNA differ from those for the synthesis of RNA in two respects. In DNA the purine and pyrimidine nucleotides contain the pentose sugar 2-deoxyribose instead of ribose. In addition, the pyrimidine base uracil, found in RNA, is replaced in DNA by thymine. The deoxyribonucleoside diphosphate can be derived directly from the corresponding ribonucleoside diphosphate by a process involving the two sulfhydryl groups of the protein, thioredoxin, and a flavoprotein, thioredoxin reductase, that can in turn be reduced by reduced $NADP^+$. Thus, for the reduction of XDP, in which X represents a purine base or cytosine, the reaction may be written as shown in [75a] and [75b]. In [75a] oxidized thioredoxin-S_2 is reduced to thioredoxin-$(SH)_2$ by NADPH, which is oxidized in the process. Thioredoxin-$(SH)_2$ then reduces XDP to deoxyXDP in a reaction [75b] in which thioredoxin is re-formed.

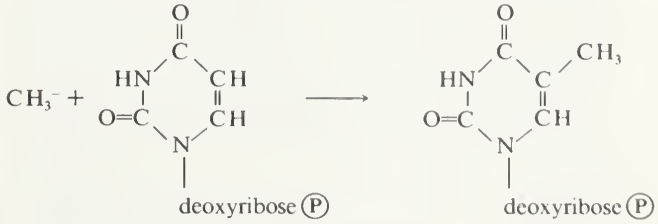
Deoxythymidylic acid (dTMP) is derived from deoxyuridylic acid (dUMP). Deoxyuridine diphosphate



dUMP dTMP [76]

Deoxythymidylic acid

(dUDP) is first converted to dUMP, by reaction [69] proceeding from right to left. Deoxyuridylic acid then accepts a methyl group (CH_3-) in a reaction catalyzed by an enzyme (thymidylate synthetase) with the vitamin folic acid as a coenzyme; the product is dTMP [76].

THE SYNTHESIS OF MACROMOLECULES

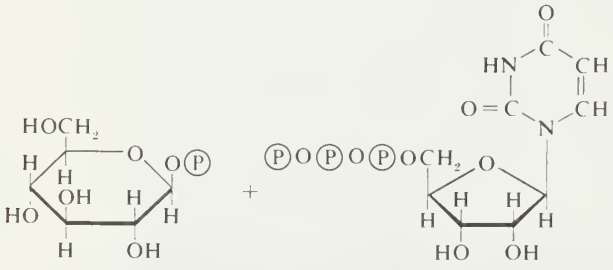
Carbohydrates and lipids. The formation of polysaccharides and of phospholipids from their component building blocks not only requires the investment of the energy of nucleoside triphosphates but uses these molecules in a novel manner. The biosynthetic reactions described thus far have mainly been accompanied by the formation of energy-rich intermediates (*e.g.*, PEP in [56]) with the formation of either AMP or ADP; however, nucleotides serve as intermediate carriers in the formation of glycogen, starch, and a variety of lipids. This unique process necessitates reactions by which ATP, or another nucleoside triphosphate, which can be readily derived from ATP via reactions of type [43a], combines with a phosphorylated reactant to form a nucleoside-diphosphate product. Although the change in standard free energy is small in this reaction, the subsequent hydrolysis of the inorganic pyrophosphate also released (reaction [21a]) effectively makes the reaction irreversible in the direction of synthesis. The nucleoside triphosphate is represented as NTP in [77], and the phosphorylated reactant as R—Ⓟ.

$$NTP + R-\textcircled{P} \rightleftharpoons NDP-R + PP_i \qquad [77]$$

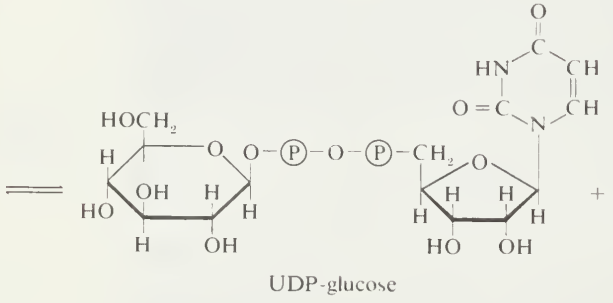
Reactions of type [77] are catalyzed by pyrophosphorylases, reaction [21a] by inorganic pyrophosphatase.

Glycogen and starch

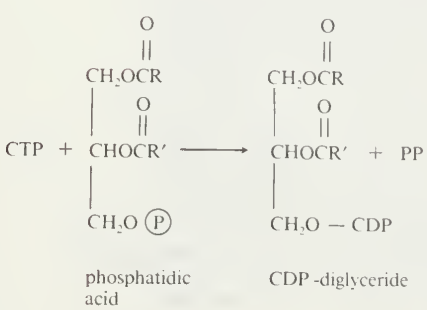
Formation of storage polysaccharides. In the formation of storage polysaccharides—*i.e.*, glycogen in animals, starch in plants—reaction [77] is preceded by the conversion of glucose 6-phosphate to glucose 1-phosphate, in a reaction catalyzed by phosphoglucomutase [78]. Glucose 1-phosphate functions as R—Ⓟ in reaction [77a]. UTP is the specific NTP for glycogen synthesis in animals



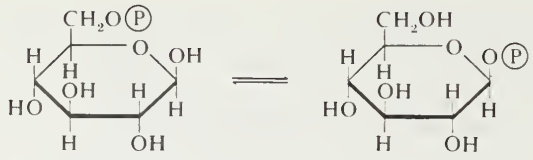
glucose 1-phosphate UTP [77a]



UDP-glucose



phosphatidic acid CDP-diglyceride [77b]



glucose 6-phosphate glucose 1-phosphate [78]

[77a]; the products are UDP-glucose and pyrophosphate. In bacteria, fungi, and plants, ATP, CTP, or GTP serves instead of UTP. In all cases the nucleoside diphosphate glucose (NDP-glucose) thus synthesized can donate glucose to the terminal glucose of a polysaccharide chain, thereby increasing the number (n) of glucose molecules by one to $n + 1$[79]. UDP is released in this process, which is catalyzed by glycogen synthetase. Starch synthesis in plants occurs by an analogous pathway catalyzed by amylose synthetase; ADP-glucose rather than UDP-glucose is the preferred glucose donor [79a]. Similarly, cellulose, the major structural polysaccharide in plant cell walls, is synthesized in some plants by reaction [79a]; other plants undergo analogous reactions in which GDP-glucose or CDP-glucose acts as the glucose donor.

$$\text{ADP-glucose} + (\text{glucose})_n \longrightarrow \text{ADP} + (\text{glucose})_{n+1} \qquad [79a]$$

Nucleoside diphosphate sugars also participate in the synthesis of disaccharides; for example, common table sugar, sucrose (consisting of glucose and fructose), is formed in sugarcane by the reaction sequence shown in [80] and [81];

$$\text{UDP-glucose} + \text{fructose 6-phosphate} \longrightarrow \text{UDP} + \text{sucrose 6′-phosphate} \qquad [80]$$

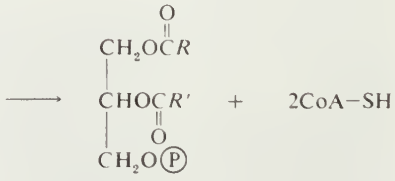
$$\text{sucrose 6′-phosphate} + H_2O \longrightarrow \text{sucrose} + P_i \qquad [81]$$

UDP-glucose and fructose 6-phosphate first form a phosphorylated derivative of sucrose, sucrose 6′-phosphate, which is hydrolyzed to sucrose and inorganic phosphate. Lactose, which consists of galactose and glucose, is the principal sugar of milk. It is synthesized in the mammary gland as shown in [82]; UDP-galactose and glucose react to form lactose; UDP is also a product.

$$\text{UDP-galactose} + \text{glucose} \longrightarrow \text{UDP} + \text{lactose} \qquad [82]$$

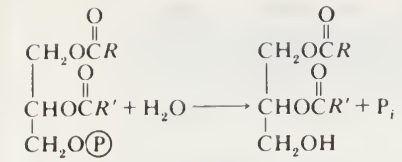
Formation of lipids. The neutral fats, or triglycerides, that constitute storage lipids, and the phospholipid components of lipoproteins and membranes, are synthesized from their building blocks by a route that branches after the first biosynthetic reaction. Initially, one molecule of glycerol 1-phosphate, the intermediate derived from carbohydrate catabolism, and two molecules of the appropriate fatty acyl coenzyme A (formed as described above, under *Biosynthesis of lipid components*) combine,

glycerol 1-phosphate acyl coenzyme A [83]

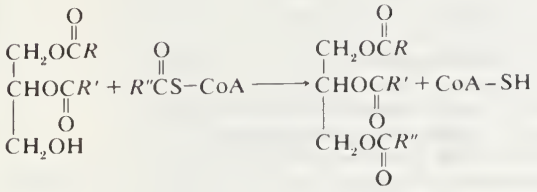


phosphatidic acid

yielding phosphatidic acid [83]. This reaction occurs preferentially with acyl coenzyme A derivatives of fatty acids containing 16 or 18 carbon atoms. In reaction [83], R and R' represent the hydrocarbon moieties ($Ch_3(CH_2)_n-$) of two fatty acid molecules. A triglyceride molecule (neutral fat) is formed from phosphatidic acid in a reaction catalyzed by a phosphatase that results in loss of the



phosphatidic acid diglyceride [84]



diglyceride triglyceride [84a]

phosphate group [84]; the diglyceride thus formed can then accept a third molecule of fatty acyl coenzyme A (represented as $R''CS-CoA$ in [84a]).

Biosynthesis of phospholipids

In the biosynthesis of phospholipids, however, phosphatidic acid is not hydrolyzed; rather, it acts as the R—Ⓟ in reaction [77], the NTP here being cytidine triphosphate (CTP). A CDP-diglyceride is produced, and inorganic pyrophosphate is released [77b]. CDP-diglyceride is the common precursor of a variety of phospholipids. In subsequent reactions, each catalyzed by a specific enzyme, CMP is displaced from CDP-diglyceride by one of three compounds—serine, inositol, or glycerol 1-phosphate—to form CMP and, respectively, phosphatidylserine [85a], phosphatidylinositol [85b], or, in [85c], 3-phosphatidyl-glycerol 1′-phosphate (PGP). These reactions differ from those of polysaccharide biosynthesis ([79], [82]) in that phosphate is retained in the phospholipid, and the nucleotide product (CMP) is therefore a nucleoside monophosphate rather than the diphosphate. These compounds can react further: phosphatidylserine to give, sequentially, phosphatidylethanolamine and phosphatidylcholine; phosphatidylinositol to yield mono- and diphosphate derivatives that are components of brain tissue and of mitochondrial membranes; and PGP to yield the phosphatidylglycerol abundant in many bacterial membranes and the diphosphatidylglycerol that is also a major component of mitochondrial and bacterial membranes.

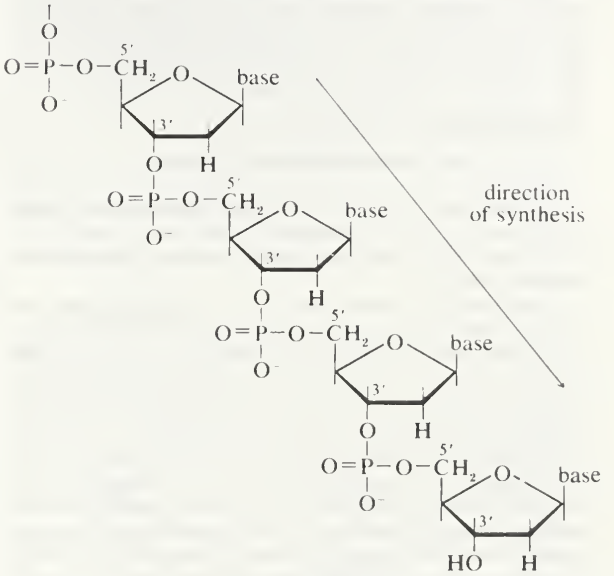
CDP-diglyceride + inositol ⟶ phosphatidylinositol + CMP [85b]

CDP-diglyceride + glycerol 1-phosphate ⟶ PGP + CMP [85c]

Formation of nucleic acids

Nucleic acids and proteins. As with the synthesis of polysaccharides and lipids, the formation of the nucleic acids and proteins from their building blocks requires the input of energy. Nucleic acids are formed from nucleoside triphosphates, with concomitant elimination of inorganic pyrophosphate, which is subsequently hydrolyzed via reaction [21a]. Amino acids also are activated, forming, at the expense of ATP, aminoacyl-complexes. This activation process is also accompanied by loss of inorganic pyrophosphate. But, although these biochemical processes are basically similar to those involved in the biosynthesis of other macromolecules, their occurrence is specifically subservient to the genetic information in DNA. DNA contains within its structure the blueprint both for its own exact duplication and for the synthesis of a number of types of RNA, among which is a class termed messenger RNA (mRNA). A complementary relationship exists between the sequence of purines (*i.e.*, adenine and guanosine) and pyrimidines (cytosine and thymine) in the DNA comprising a gene and the sequence in mRNA into which this genetic information is transcribed. This information is then translated into the sequence of amino acids in a protein, a process that involves the functioning of a variety of other classes of ribonucleic acids (see GENETICS AND HEREDITY, THE PRINCIPLES OF).

Synthesis of DNA. The maintenance of genetic integrity demands not only that enzymes exist for the synthesis of DNA but that they function so as to ensure the replication of the genetic information (encoded in the DNA to be copied) with absolute fidelity. This implies that the assembly of new regions of a DNA molecule must occur on a template of DNA already present in the cell. The synthetic processes must also be capable of repairing limited regions of DNA, which may have been damaged, for example, as a consequence of exposure to ultraviolet irradiation. The physical structure of DNA is ideally adapted to its biological roles. Two strands of nucleotides are wound around each other in the form of a double helix. The helix is stabilized by hydrogen bonds that occur between the purine and pyrimidine bases of the strands. Thus, the adenine of one strand pairs with the thymine of the other, and the guanine of one strand with the cytosine of the other. The base pairs may be visualized as the treads of a spiral staircase, in which the two chains of repeating units (*i.e.*, ribose-phosphate-ribose) form the sides.



DNA strand

Biosynthesis of DNA

During the biosynthesis of DNA, the two strands unwind, and each serves as a template for the synthesis of a new, complementary strand, in which the bases pair in exactly the same manner as occurred in the parent double helix. The process is catalyzed by a DNA polymerase enzyme, which catalyzes the addition of the appropriate deoxyribonucleoside triphosphate (NTP) in [86] onto one end, specifically, the free 3′-hydroxyl end (—OH) of the growing DNA chain (see diagram of DNA strand). In [86] the addition of a deoxyribonucleoside monophosphate (dNMP) moiety onto a growing DNA chain (5′-DNA-polymer-3′-OH) is shown; the other product is inorganic pyrophosphate. The specific nucleotide inserted in the growing chain is dictated by the base in the complementary (template) strand of DNA with which it pairs. The functioning of DNA polymerase thus requires the presence of all four deoxyribonucleoside triphosphates (*i.e.*, dATP, dTPP, dGTP, and dCTP) as well as preformed DNA to act as a template. Although a number of DNA polymerase enzymes have been purified from different organisms, it is not yet certain whether those that have been most extensively studied are necessarily involved in the formation of new DNA molecules, or whether they are primarily concerned with the repair of damaged regions of molecules. A polynucleotide ligase that effects the formation of the phosphate bond between adjacent sugar molecules is concerned with the repair function but may also have a role in synthesis.

5′-DNA-polymer-3′-OH + dNTP ⟶ 5′-DNA-polymer-dNMP-3′-OH + PP [86]

The varieties of RNA

Synthesis of RNA. Various types of RNA are found in living organisms: messenger RNA (mRNA) is involved in the immediate transcription of regions of DNA; transfer RNA (tRNA) is concerned with the incorporation of amino acids into proteins; and structural RNA is found in the ribosomes that form the protein-synthesizing machinery of the cell. In cells of organisms with well-defined nuclei (*i.e.,* eukaryotes), a heterogenous RNA fraction of unknown function is constantly broken down and resynthesized in the nucleus of the cell but does not leave it. The different types of RNA are synthesized via RNA polymerases [87], the action of which is analogous to that of the DNA polymerases that catalyze reaction [86]. In [87] the growing RNA chain is represented by 5′-RNA-polymer-3′-OH, and the ribonucleoside triphosphate by NTP. One product (5′-RNA-polymer-NMP-3′-OH) reflects the incorporation of ribonucleoside monophosphate; the other product is, as in [86], inorganic pyrophosphate. Synthesis of RNA requires DNA as a template, thus ensuring that the base composition of the RNA faithfully reflects that of the DNA; in addition, as in DNA synthesis, all four nucleoside triphosphates must be present. The major differences between reactions [86] and [87] are that, in the latter, the nucleotides contain ribose instead of deoxyribose, and that, in RNA, uracil replaces the thymine of DNA.

$$\text{5′-RNA-polymer-3′-OH} + \text{NTP} \longrightarrow \text{5′-RNA-polymer-NMP-3′-OH} + \text{PP}_i \qquad [87]$$

It appears that, although only one strand of the DNA double helix serves as template during the formation of RNA, some regions are transcribed from one strand, some from the other.

An important constraint on RNA synthesis is that the accurate copying of the appropriate DNA strand by RNA polymerase must start at the beginning of a gene—and not somewhere along it—and must stop as soon as the genetic information has been transcribed. The way in which this selectivity is achieved is not yet fully understood, although it has been established that *E. coli* contains a protein, the sigma factor, that is not required for the incorporation of the nucleoside triphosphates into the growing RNA chain but apparently is essential for binding RNA polymerase to the proper DNA sites to initiate RNA synthesis. After the initiation step, the sigma factor is released; the role of the sigma factor in transcription suggests that the DNA at the initiation sites must be unique in some way so as to ensure that the correct strand is used as the template. Evidence indicates further that other protein factors are involved in the termination of transcription.

Synthesis of proteins. Approximately 120 macromolecules are involved directly or indirectly in the process of the translation of the base sequence of a messenger RNA molecule into the amino-acid sequence of a protein. The relationship between the base sequence and the amino-acid sequence constitutes the genetic code. The basic properties of the code are: it is triplet—*i.e.,* a linear sequence of three bases in mRNA specifies one amino acid in a protein; it is nonoverlapping—*i.e.,* each triplet is discrete and does not overlap either neighbour; it is degenerate—*i.e.,* many of the 20 amino acids are specified by more than one of the 64 possible triplets of bases; and it appears to apply universally to all living organisms.

The main sequence of events associated with the expression of this genetic code, as elucidated for *E. coli,* may be summarized as follows (see also GENETICS AND HEREDITY, THE PRINCIPLES OF).

1. Messenger RNA binds to the smaller of two subunits of large particles termed ribosomes.

2. The amino acid that begins the assembly of the protein chain is activated and transferred to a specific transfer RNA (tRNA). The activation step, catalyzed by an aminoacyl–tRNA synthetase specific for a particular amino acid, effects the formation of an aminoacyl–AMP complex [88a] in a manner somewhat analogous to reaction [77]; ATP is required, and inorganic pyrophosphate is a product. The aminoacyl–AMP, which remains bound to the enzyme, is transferred to a specific molecule of tRNA in a reaction catalyzed by the same enzyme. AMP is released, and the other product is called aminoacyl–tRNA [88b]. In *E. coli* the amino acid that begins the assembly of the protein is always formylmethionine (f-Met). There is no evidence that f-Met is involved in protein synthesis in eukaryotic cells.

$$\text{amino acid} + \text{ATP} \longrightarrow \underset{\text{aminoacyl–AMP}}{\text{aminoacyl}-\text{Ⓟ}-\text{ribose}-\text{adenine}} + \text{PP}_i \qquad [88a]$$

$$\text{aminoacyl}-\text{AMP} + \text{tRNA} \longrightarrow \text{aminoacyl}-\text{tRNA} + \text{AMP} \qquad [88b]$$

Translation

3. Aminoacyl–tRNA binds to the mRNA-ribosomal complex in a reaction in which energy is provided by the hydrolysis of GTP to GDP and inorganic phosphate. In this step and in 5 below, the genetic code is translated. All of the different tRNAs contain triplets of bases that pair specifically with the complementary base triplets in mRNA; the base triplets in mRNA specify the amino acids to be added to the protein chain. During or shortly after the pairing occurs the aminoacyl–tRNA moves from the aminoacyl-acceptor (A) site on the ribosome to another site, called a peptidyl-donor (P) site.

4. The larger subunit of the ribosome then joins the mRNA–f-Met–tRNA–smaller ribosomal subunit complex.

5. The second amino acid to be added to the protein chain is specified by the triplet of bases adjacent to the initiator triplet in mRNA. The amino acid is activated and transferred to its tRNA by a repetition of reactions [88a] and [88b]. This newly formed aminoacyl–tRNA now binds to the A site of the mRNA–ribosome complex, with concomitant hydrolysis of GTP.

6. The enzyme peptidyl transferase, which is part of the larger of the two ribosomal subunits, catalyzes the transfer of formylmethionine from the tRNA to which it is attached (designated $tRNA^{f\text{-}Met}$) to the second amino acid; for example, if the second amino acid were leucine, step 5 would have achieved the binding of leucyl–tRNA ($Leu\text{–}tRNA^{Leu}$) next to $f\text{-Met–}tRNA^{f\text{-}Met}$ on the ribosome–mRNA complex. Step 6 catalyzes the transfer reaction that is shown in [89], in which $tRNA^{f\text{-}Met}$ is released from formyl-methionine (f-Met), and $Leu\text{–}tRNA^{Leu}$ is bound to formyl-methionine.

$$f\text{-Met}-tRNA^{f\text{-Met}} + Leu-tRNA^{Leu} \longrightarrow f\text{-Met}-Leu-tRNA^{Leu} + tRNA^{f\text{-Met}} \qquad [89]$$

7. In the next step three results are achieved. The dipeptide f-Met–Leu (a dipeptide consists of two amino acids) moves from the A (aminoacyl-acceptor) site to the P (peptidyl-donor) site on the ribosome; the $tRNA^{f\text{-}Met}$ is thereby displaced from the P site, and the ribosome moves the length of one triplet (three bases) along the mRNA molecule. The occurrence of these events is accompanied by the hydrolysis of a second molecule of GTP and leaves the system ready to receive the next aminoacyl–tRNA (by repetition of step 5). The cycle of events in 5, 6, and 7 is repeated until the ribosome moves to a triplet on the mRNA that does not specify an amino acid but provides the signal for termination of the amino-acid chain. Triplets of this type are represented by one uracil (U) preceding, and adjacent to, two adenines (UAA) or preceding one adenine and one guanosine in either order (UGA, or UAG).

Termination of the amino-acid chain

8. At the termination of synthesis the completed protein is released from the tRNA to which it had remained linked. Two further events then occur in *E. coli.* First, the formyl constituent of the f-methionyl moiety is hydrolyzed by the catalytic action of a formylase, producing a protein with methionine at the end. If the required protein does not contain methionine in this position (and the majority of proteins in *E. coli* appear to), the methionine and possibly other amino acids that follow it are removed by enzymatic reactions. Second, the ribosome–mRNA complex dissociates, and the ribosomal subunits become available for a new round of translation by binding another mRNA molecule, step 1.

For the sake of brevity, other ancillary protein factors that participate in this sequence 1 to 8 have been omitted; the role of many of these factors is as yet poorly understood.

Regulation of metabolism

FINE CONTROL

The flux of nutrients along each metabolic pathway is governed chiefly by two factors: (1) the availability of substrates on which pacemaker, or key, enzymes of the pathway can act and (2) the intracellular levels of specific metabolites that affect the reaction rates of pacemaker enzymes. Key enzymes are usually complex proteins that, in addition to the site at which the catalytic process occurs (*i.e.,* the active site), contain sites to which the regulatory metabolites bind. Interactions with the appropriate molecules at these regulatory sites cause changes in the shape of the enzyme molecule. Such changes may either facilitate or hinder the changes that occur at the active site. The rate of the enzymatic reaction is thus speeded up or slowed down by the presence of a regulatory metabolite.

In many cases, the specific small molecules that bind to the regulatory sites have no obvious structural similarity to the substrates of the enzymes; these small molecules are therefore termed allosteric effectors, and the regulatory sites are termed allosteric sites (see the article BIOCHEMICAL COMPONENTS OF ORGANISMS). Allosteric effectors may be formed by enzyme-catalyzed reactions in the same pathway in which the enzyme regulated by the effectors functions. In this case a rise in the level of the allosteric effector would affect the flux of nutrients along that pathway in a manner analogous to the feedback phenomena of homeostatic processes. Such effectors may also be formed by enzymatic reactions in apparently unrelated pathways. In this instance the rate at which one metabolic pathway operates would be profoundly affected by the rate of nutrient flux along another. It is this situation that, to a large extent, governs the sensitive and immediately responsive coordination of the many metabolic routes in the cell.

End-product inhibition. A biosynthetic pathway is usually controlled by an allosteric effector produced as the end product of that pathway, and the pacemaker enzyme on which the effector acts usually catalyzes the first step that uniquely leads to the end product. This phenomenon, called end-product inhibition, is illustrated by the multienzyme, branched pathway for the formation from oxaloacetate of the "aspartate family" of amino acids (Figure 10). The system of interlocking controls is described in greater detail in Figure 12. As mentioned previously in this article, only plants and microorganisms can synthesize many of these amino acids, most animals requiring such amino acids to be supplied preformed in their diets.

Figure 12 shows that there are a number of pacemaker enzymes in the biosynthetic route for the aspartate family of amino acids, most of which are uniquely involved in the formation of one product. Each of the enzymes functions after a branch point in the pathway, and all are inhibited specifically by the end product that emerges from the branch point. It is not difficult to visualize from Figure 12 how the supplies of lysine, methionine, and isoleucine required by a cell can be independently regulated. Threonine, however, is both an amino acid essential for protein synthesis and a precursor of isoleucine. If the rate of synthesis of threonine from aspartate were regulated as are the rates of lysine, methionine, and isoleucine, an imbalance in the supply of isoleucine might result. This risk is overcome in *E. coli* by the existence of three different aspartokinase enzymes, all of which catalyze the first step common to the production of all the products derived from aspartate. Each has a different regulatory effector molecule. Thus, one type of aspartokinase is inhibited by lysine, a second by threonine. The third kinase is not inhibited by any naturally occurring amino acid, but its rate of synthesis (see below) is controlled by the concentration of methionine within the cell. The triple control mechanism resulting from the three different aspartokinases ensures that the accumulation of one amino acid does not shut off the supply of aspartyl phosphate necessary for the synthesis of the others.

Another example of control through end-product inhibition also illustrates the manner in which the operation of two biosynthetic pathways may be coordinated. Both DNA and the various types of RNA are assembled from purine and pyrimidine nucleotides (see above *Nucleic acids and proteins*); these in turn are built up from intermediates of central metabolic pathways (see above *Mononucleotides*). The first step in the synthesis of pyrimidine nucleotides is that catalyzed by aspartate carbamoyltransferase [70a]. This step initiates a sequence of reactions that leads to the formation of pyrimidine nucleotides such as UTP and CTP [74]. Studies of aspartate carbamoyltransferase have revealed that the affinity of this enzyme for its substrate (aspartate) is markedly decreased by the presence of CTP. This effect can be overcome by the addition of ATP, a purine nucleotide. The enzyme can be dissociated into two subunits: one contains the enzymatic activity and (in the dissociated form) does not bind CTP; the other binds CTP but has no catalytic activity. Apart from providing physical evidence that pacemaker enzymes contain distinct catalytic and regulatory sites, the interaction of aspartate carbamoyltransferase with the different nucleotides provides an explanation for the control of the supply of nucleic acid precursors. If a cell contains sufficient pyrimidine nucleotides (*e.g.,* UTP), aspartate carbamoyltransferase, the first enzyme of pyrimidine biosynthesis, is inhibited. If, however, the cell contains high levels of purine nucleotides (*e.g.,* ATP), as required for the formation of nucleic acids, the inhibition of aspartate carbamoyltransferase is relieved, and pyrimidines are formed.

Aspartate carbamoyltransferase

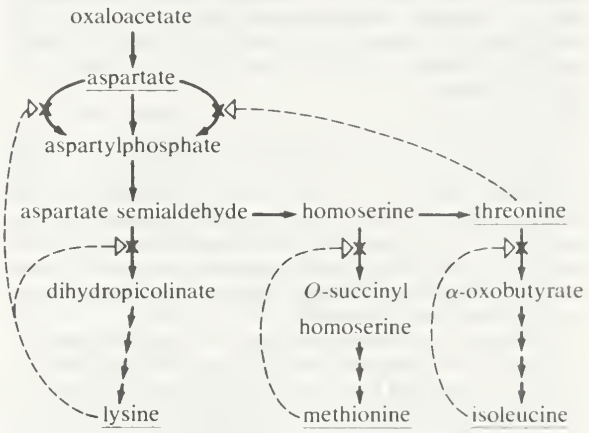


Figure 12: "Fine control" of the enzymes of the aspartate family in *E. coli* (see text).

Positive modulation. Not all pacemaker enzymes are controlled by inhibition of their activity. Instead, some are subject to positive modulation—*i.e.,* the effector is required for the efficient functioning of the enzyme. Such enzymes exhibit little activity in the absence of the appropriate allosteric effector. One instance of positive modulation is the anaplerotic fixation of carbon dioxide onto pyruvate and phosphoenolpyruvate (PEP); this example also illustrates how a metabolic product of one route controls the rate of nutrient flow of another (see Figure 9).

The carboxylation of pyruvate in higher organisms [50] and the carboxylation of phosphoenolpyruvate in gut bacteria [50a] occurs at a significant rate only if acetyl coenzyme A is present. Acetyl coenzyme A acts as a positive allosteric effector and is not broken down in the course of the reaction. Moreover, some pyruvate carboxylases [50] and the PEP carboxylase of gut bacteria are inhibited by four-carbon compounds (*e.g.,* aspartate). These substances inhibit because they interfere with the binding of the positive effector, acetyl coenzyme A. Such enzymatic controls are reasonable in a physiological sense: it will be recalled that anaplerotic formation of oxaloacetate from pyruvate or PEP is required to provide the acceptor for the entry of acetyl coenzyme A into the TCA cycle. The reaction need occur only if acetyl coenzyme A is present in sufficient amounts. On the other hand, an abundance of four-carbon intermediates obviates the necessity for forming more through carboxylation reactions such as [50] and [50a].

Similar reasoning, though in the opposite sense, can be applied to the control of another anaplerotic sequence, the glyoxylate cycle (Figure 8). The biosynthesis of cell materials from the two-carbon compound acetate is, in principle, akin to biosynthesis from TCA cycle intermediates. In both processes, it is the availability of intermediates such as PEP and pyruvate that determines the rate at which a cell forms the many components produced through gluconeogenesis. Although in the strictest sense the glyoxylate cycle has no defined end product, PEP and pyruvate are, for these physiological reasons, best fitted to regulate the rate at which the glyoxylate cycle is required to operate. It is thus not unexpected that the pacemaker enzyme of the glyoxylate cycle, isocitrate lyase (reaction [52]), is allosterically inhibited by PEP and by pyruvate.

Rate of the glyoxylate cycle

Energy state of the cell. It is characteristic of catabolic routes that they do not lead to uniquely identifiable end products. The major products of glycolysis and the TCA cycle, for example, are carbon dioxide and water. Within the cell, the concentrations of both are unlikely to vary sufficiently to allow them to serve as effective regulatory metabolites. The processes by which water is produced (Figure 7) initially involve, however, the reduction of coenzymes, the reoxidation of which is accompanied by the synthesis of ATP from ADP. Moreover, as described in previous sections, the utilization of ATP in energy-consuming reactions yields ADP and AMP. At any given moment, therefore, a living cell contains ATP, ADP, and AMP; the relative proportion of the three nucleotides provides an index of the energy state of the cell. It is thus reasonable that the flux of nutrients through catabolic routes is, in general, impeded by high intracellular levels of both reduced coenzymes (*e.g.*, $FADH_2$, reduced NAD^+) and ATP, and that these inhibitory effects are often overcome by AMP.

The control exerted by the levels of ATP, ADP, and AMP within the cell is illustrated by the regulatory mechanisms of glycolysis and the TCA cycle (Figure 9); these nucleotides also serve to govern the occurrence of the opposite pathway, gluconeogenesis, and to avoid mutual interference of the catabolic and anabolic sequences. Although not all of the controls mentioned below have been found to operate in all living organisms examined, it has been observed that, in general:

1. Glucose 6-phosphate stimulates glycogen synthesis from glucose 1-phosphate [79] and inhibits both glycogen breakdown [16] and its own formation from glucose [1].

2. Phosphofructokinase, the most important pacemaker enzyme of glycolysis [3], is inhibited by high levels of its own substrates (fructose 6-phosphate and ATP); this inhibition is overcome by AMP. In tissues, such as heart muscle, which use fatty acids as a major fuel, inhibition of glycolysis by citrate may be physiologically the more important means of control. Control by citrate, the first intermediate of the TCA cycle, which produces the bulk of the cellular ATP, is thus the same, in principle, as control through ATP.

3. Fructose 1,6-diphosphatase [59], which catalyzes the reaction opposite to phosphofructokinase, is strongly inhibited by AMP.

4. Rapid catabolism of carbohydrate requires the efficient conversion of PEP to pyruvate. In liver and in some bacteria the activity of the pyruvate kinase that catalyzes this process [10] is greatly stimulated by the presence of fructose 1,6-diphosphate, which thus acts as a potentiator of a reaction required for its ultimate catabolism.

Inhibition of pyruvate oxidation

5. The oxidation of pyruvate to acetyl coenzyme A [37] is inhibited by acetyl coenzyme A. Because acetyl coenzyme A also acts as a positive modulator of pyruvate carboxylation [50], this control reinforces the partition between pyruvate catabolism and its conversion to four-carbon intermediates for anaplerosis and gluconeogenesis.

6. Citrate synthase [38], the first enzyme of the TCA cycle, is inhibited by ATP in higher organisms and by reduced NAD^+ in many microorganisms. In some strictly aerobic bacteria, the inhibition by reduced NAD^+ is overcome by AMP.

7. Citrate acts as a positive effector for the first enzyme of fatty acid biosynthesis [62]. A high level of citrate, which also indicates a sufficient energy supply, thus inhibits carbohydrate fragmentation (see [2]) and diverts the carbohydrate that has been fragmented from combustion to the formation of lipids.

8. Some forms of isocitrate dehydrogenase [40] are maximally active only in the presence of ADP or AMP and are inhibited by ATP. This is an example of regulation by covalent modification of an enzyme since the action of ATP here is to phosphorylate, and consequently to inactivate, the isocitrate dehydrogenase. A specific phosphatase, which is a different enzymatic activity of the protein that effects the phosphorylation by ATP, catalyzes the splitting-off by water of the phosphate moiety on the inactive isocitrate dehydrogenase and thus restricts activity. Again, the energy state of the cell serves as the signal regulating an enzyme involved in energy transduction.

COARSE CONTROL

Although fine control mechanisms allow the sensitive adjustment of the flux of nutrients along metabolic pathways relative to the needs of cells under relatively constant environmental conditions, these processes may not be adequate to cope with severe changes in the chemical milieu.

Such severe changes may arise in higher organisms with a change in diet or when, in response to other stimuli, the hormonal balance is altered (see BIOCHEMICAL COMPONENTS OF ORGANISMS). In starvation, for example, the overriding need to maintain blood glucose levels may require the liver to synthesize glucose from noncarbohydrate products of tissue breakdown at rates greater than can be achieved by the enzymes normally present in the liver. Under such circumstances, cellular concentrations of key enzymes of gluconeogenesis, such as pyruvate carboxylase [50] and PEP carboxykinase [54], may rise by as much as 10-fold, while the concentration of glucokinase [1] and of the enzymes of fatty acid synthesis decreases to a similar extent. Conversely, high carbohydrate diets and administration of the hormone insulin to diabetic animals elicit a preferential synthesis of glucokinase [1] and pyruvate kinase [10]. These changes in the relative proportions and absolute amounts of key enzymes are the net result of increases in the rate of their synthesis and decreases in the rate of their destruction. Although such changes reflect changes in the rates of either transcription, translation, or both of specific regions of the genome, the mechanisms by which the changes are effected have not yet been clarified.

Microorganisms sometimes encounter changes in environment much more severe than those encountered by the cells of tissues and organs, and their responses are correspondingly greater. Mention has already been made of the ability of *E. coli* to form β-galactosidase when transferred to a medium containing lactose as the sole carbon source (see *Integration of catabolism and anabolism*); such a transfer may result in an increase of 1,000-fold or more in the cellular concentration of the enzyme. Because this preferential enzyme synthesis is elicited by exposure of the cells to lactose, or to non-metabolizable but chemically similar analogues, and because synthesis ceases as soon as the eliciting agents (inducers) are removed, β-galactosidase is termed an inducible enzyme. It has been established that a regulator gene exists that specifies the amino-acid sequence of a so-called repressor protein, and that the repressor protein binds to a unique portion of the region of DNA concerned with β-galactosidase formation. Under these circumstances the DNA is not transcribed to mRNA, and virtually no enzyme is made. The repressor, however, is an allosteric protein and readily combines with inducers. Such a combination prevents the repressor from binding to DNA and allows transcription and translation of β-galactosidase to proceed.

β-galactosidase

Although this mechanism for the specific control of gene activity may not apply to the regulation of all inducible enzymes—for example, those concerned with the utilization of the sugar arabinose—and is not universally applicable to all coarse control processes in all microorganisms, it can explain the manner in which the presence in growth media of at least some cell components represses (*i.e.*, inhibits the synthesis of) enzymes normally involved in the formation of such components by gut bacteria such

as *E. coli*. Although, for example, the bacteria must obviously make amino acids from ammonia if that is the sole source of nitrogen available to them, it would not be necessary for the bacteria to synthesize enzymes required for the formation of amino acids supplied preformed in the medium. Thus, of the three aspartokinases formed by *E. coli* (Figure 12), two are repressed by their end products, methionine and lysine. On the other hand, the third aspartokinase, which (as described above) is inhibited by threonine, is repressed by threonine only if isoleucine is also present. This example of so-called multivalent repression is of obvious physiological utility. It is likely that the amino acids that thus specifically inhibit the synthesis of aspartokinases do so by combining with specific protein repressor molecules; however, whereas the combination of the inducer with the repressor of β-galactosidase inactivates the repressor protein and hence permits synthesis of the enzyme, the repressor proteins for biosynthetic enzymes would not bind to DNA unless they were also combined with the appropriate amino acid. Aspartokinase synthesis would thus occur in the absence of the end-product effectors and not in their presence.

This explanation applies also to the coarse control of the anaplerotic glyoxylate cycle (Figure 8). The synthesis of both of the enzymes unique to that cycle, isocitrate lyase [52] and malate synthase [53], is controlled by a regulator gene that presumably specifies a repressor protein unable to bind to DNA unless combined with pyruvate or PEP. Cells growing on acetate do not contain high levels of these intermediates because they are continuously being removed for biosynthesis. The enzymes of the glyoxylate cycle are therefore formed at high rates. If pyruvate or substances catabolized to PEP or pyruvate are added to the medium, however, further synthesis of the two enzymes is speedily repressed. (Ha.Ko.)

Metabolic diseases

GENERAL CONSIDERATIONS

Metabolic diseases are conditions caused by an abnormality in one or more of the chemical reactions essential to producing energy, to regenerating cellular constituents, or to eliminating unneeded products arising from these processes. Depending on which metabolic pathway is involved, a single defective chemical reaction may produce consequences that are narrow, involving a single body function, or broad, affecting many organs and systems.

In addition to the fine and coarse mechanisms that affect individual chemical reactions (see above *Regulation of metabolism*), the rate and direction of metabolic processes are regulated by the availability of substrates (particularly essential amino acids or fatty acids), cofactors (whose presence is required to assist the enzyme), and key minerals; and by the influence of hormones secreted by endocrine glands and tissues. Abnormalities in any of these areas affect the many metabolic pathways that are driven by the catalytic activities of different enzymes. Nutritional and endocrine diseases are, in fact, the most common causes of metabolic dysfunction (see ENDOCRINE SYSTEMS), and diseases involving thyroid hormones and insulin, as well as caloric deprivation, illustrate the impact such abnormalities may have on the overall metabolic cycle.

The thyroid gland secretes two hormones, thyroxine and triiodothyronine, that regulate the overall rate of oxygen utilization and hence the production of useful energy from the combustion of food. When an excess of thyroid hormone is present (hyperthyroidism), the rate of oxidation of sugars, fatty acids, and amino acids is above normal. Simultaneously, as more oxygen is used, more carbon dioxide (CO_2) and urea are formed as the end products of metabolism. The demands for calories to supply the extra substrates and of vitamins as enzyme cofactors increase. Despite this, there is usually a loss of body weight from both fat and muscle tissue, the latter composed primarily of protein. Much of the extra energy generated is in the form of heat, and perspiration and evaporation of water are increased in order to maintain normal body temperature. Because the body requires more oxygen, the rates of respiration and blood flow increase to allow the extra oxygen to be delivered to tissues and to remove the extra carbon dioxide. A deficiency of thyroid hormone (hypothyroidism) produces exactly the opposite effects.

Another major hormone that influences metabolism is insulin, which is secreted by special cells of the pancreas. Insulin primarily regulates the direction of metabolism, shifting many processes toward the storage of substrates and away from their degradation. Insulin acts to increase the transport of glucose and amino acids as well as key minerals such as potassium, magnesium, and phosphate from the blood into cells. It also regulates a variety of enzymatic reactions within the cells, all of which have a common overall direction, namely the synthesis of large molecules from small units. A deficiency in the action of insulin (diabetes mellitus) causes severe impairment in (1) the storage of glucose in the form of glycogen and the oxidation of glucose for energy; (2) the synthesis and storage of fat from fatty acids and their precursors and the completion of fatty-acid oxidation; and (3) the synthesis of proteins from amino acids. As a result, high levels of glucose, fatty acids, keto acid products of incomplete fatty-acid oxidation, and essential amino acids are present in the blood. (The consequences of these abnormalities in metabolism are described in ENDOCRINE SYSTEMS.) Replacements for deficient hormones and methods to eliminate or combat excess hormones have been developed.

Insulin

A fundamental example of a nutritional cause for metabolic disease is caloric deprivation. In the most extreme case of fasting, the average human can survive about 60 days by oxidizing body stores of energy. Extremely obese persons can survive up to a year without food because of greater stores of fat and protein. During fasting, blood levels of glucose are low and the oxidation of glucose is curtailed, even by the brain tissue for which it is required. The blood levels of fatty acids and of their products of combustion, keto acids, are raised; keto acids partially take the place of glucose as a substrate in the brain. As the proteins of organs are degraded and not replaced, organ function declines, eventually resulting in death. Partial deprivation of calories results in a more gradual weight loss, a decline in oxygen use and energy production, a decrease in muscle strength, and lassitude. In infants and children, growth is impaired, and they are susceptible to infection and early death. In those children in whom calories are adequate but protein is chronically deficient (kwashiorkor), growth virtually ceases and the synthesis of important proteins, such as albumin, is reduced. Low levels of protein in the blood allow water to accumulate in tissues, causing the face, extremities, and abdomen to swell (edema). The immune system produces fewer cells to combat invading organisms, leading to infection and possibly death. Less severe problems include changes in skin and hair colour and texture and delayed sexual maturation. Treatment with protein or with the missing amino acids reverses the disorder.

THE DERIVATION OF SPECIFIC METABOLIC DISORDERS

Most metabolic diseases are caused by single defects in particular biochemical pathways, defects that are due to the deficient activity of individual enzymes. Around the turn of the century a British physician, Sir Archibald Garrod, proposed that such diseases were passed through generations, and he labeled them "inborn errors of metabolism." Subsequent studies have demonstrated the mechanisms by which a biochemical defect can be inherited. Beadle and Taum studied mutations in fruit flies and microorganisms and demonstrated that a single gene controls a single type of biochemical reaction. An American chemist, Linus Pauling, and a British biochemist, Vernon Ingram, showed that a mutation may be expressed as a specific alteration in the primary structure of a single type of protein.

Inborn errors of metabolism

Each enzyme is a protein and, like other proteins, has a unique sequence of amino acids. The order of the amino acids is directed by a segment of the DNA molecule called a gene. Within the gene, a sequence of three nucleotide bases directs each amino acid. If the nucleotide bases of the gene are rearranged, deleted, or substituted, the mutant gene directs the synthesis of a mutant enzyme protein, which may have only one amino acid substituted or large

segments of amino acids rearranged. Changes in structure usually decrease or entirely eliminate an enzyme's catalytic activity, slowing the rate of the biochemical reaction catalyzed by the enzyme. As a result, the amount of the product of the reaction is low, while that of the starting material (substrate) is high (Figure 13).

The potential consequences of mutant enzymes on cellular or organ function are varied: (1) the product of the affected metabolic pathway may have a key role that is not fulfilled; (2) a metabolic pathway that is repressed by normal levels of the product may proceed, with toxic consequences, when that product is at low levels; (3) excess substrate from the affected reaction may be toxic; (4) the excess substrate may become involved in and move rapidly through an alternate metabolic pathway, and the product of this pathway may be toxic. About 170 errors of metabolism can be traced to mutations in the genetic code, and the consequences range from trivial to lethal.

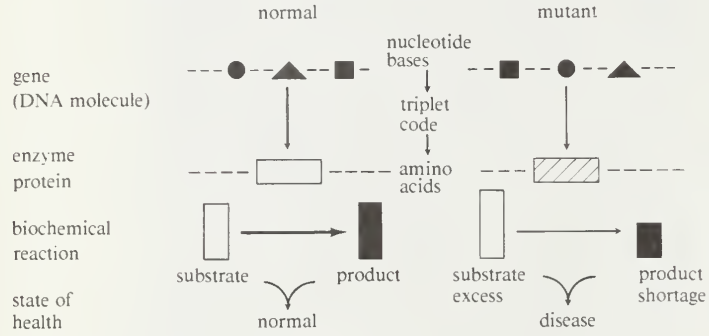

Figure 13: *Pathological sequence of inborn errors of metabolism.*
A change in the triplet nucleotide base sequence occurs at one point of the mutant gene, and the altered sequence codes for the "wrong" amino acid at a critical point in the structure of the enzyme protein. Because the mutant enzyme has little or no catalytic activity, its biochemical reaction is greatly diminished, causing a shortage of the product and an accumulation of the substrate.

Chromosomes

The nucleus holds the DNA molecules in an amorphous strand called chromatin. When the cell is ready to divide and pass along the genetic code to a newly formed cell, the chromatin condenses into 46 gene-containing units, called chromosomes, which are grouped in 23 homologous pairs. One pair determines sex (the sex chromosomes), and the remaining 22 pairs (autosomes) determine the non-sex-related features of the progeny. In fertilization, 23 chromosomes (one-half of each pair) are donated by one parent, and 23 chromosomes are donated by the other parent; the zygote (fertilized egg) then contains 23 chromosome pairs (46 chromosomes).

The effect of a mutant gene inherited from one parent depends on whether the other parent donates a similar mutant gene (homozygous) or a normal gene (heterozygous). In general, heterozygotes (those with only one mutant gene) have about 50 percent of the normal enzyme activity because only one gene is normal, although this may be sufficient to maintain good health. When, however, the gene directs the synthesis of an enzyme that is rate limiting (*i.e.*, a series of reactions will proceed at a normal rate only as long as this enzyme is available), then even a 50 percent reduction in enzyme activity may produce serious disease. This gene and the disease that results are called autosomal dominant. Homozygotes (those with two mutant genes) suffer from more severe adverse effects because the mutant enzyme has little or no normal activity. When two mutant genes must be paired to produce a disease, the gene and the disease are autosomal recessive. These basic points are summarized in Table 1.

Table 1: Hereditary Aspects of Metabolic Disease

subject	gene 1	gene 2	enzyme activity	disease	parents
normal	normal	normal	100%	no	one, both, or neither may be heterozygote
heterozygote	normal	mutant	about 50%	no if recessive, yes if dominant	one must be at least heterozygote
homozygote	mutant	mutant	near 0%	yes	both must be at least heterozygote

If the mutant gene is part of the X chromosome (a sex chromosome; females have two X chromosomes per pair, and males have an X chromosome and a Y chromosome), the disease is sex-linked. All male offspring are affected because the Y chromosome of the XY pair does not have a compensating normal gene. Because the mutation is on the X chromosome, however, and males transmit only the Y chromosome to their sons during fertilization, males do not transmit the disease to them. They do, however, transmit the carrier state (*i.e.*, the mutant X chromosome) to their daughters. If the X-linked disease is dominant, both heterozygote and homozygote females are affected, the latter more severely; if the disease is recessive, only female homozygotes are affected. Female heterozygotes transmit an X chromosome with a mutant gene to half their male offspring, prompting a disease, and an X chromosome with a mutant gene to half of their female offspring, who may in turn transmit the disease to their sons. Occasionally, only one child in a family has a metabolic disorder and there is no evidence of an abnormal gene in either parent. The abnormal gene in the child must be assumed to have arisen by a spontaneous mutation.

Two different enzyme deficiencies, operating at separate steps in the same metabolic pathway and coded for by two entirely different genes, can produce similar diseases. Alternatively, more than one type of mutant gene (allele) may have arisen at the same gene location (locus) so that diseases may arise in heterozygotes who have two different mutant genes. Some of the generalized metabolic diseases, such as diabetes, may be polygenic (*i.e.*, the disease is not fully expressed unless two or more gene loci—even on different chromosomes—are affected). Finally, certain gene-related metabolic disorders may not be expressed without a particular type of diet, hormonal stimulus, or drug.

Investigation of an inborn error

If an inborn error of metabolism is suspected, a physician can investigate at several levels: (1) a thorough family history is obtained to analyze the pattern of inheritance; (2) blood or urine is analyzed to determine whether the substrate and the product of the suspect biochemical reaction are at normal levels; (3) the activity of the suspect enzyme may be measured in red or white blood cells, in tissue samples, or in skin cells grown in test tube cultures; (4) the number of enzyme molecules may be measured in blood or tissue samples; (5) the DNA molecule that codes for the suspected abnormal enzyme may be isolated from blood cells, and its nucleotide base sequence determined and identified as mutant; and (6) testing also may be applied to parents, siblings, or offspring of the affected person. The diagnosis of a treatable condition may be made through screening at birth. A severe metabolic disorder may be diagnosed in the fetus by using samples from the amniotic fluid surrounding the embryo. The information is then available for counseling or sometimes for initiating treatment before birth.

There are a variety of treatments for metabolic disorders: (1) If the product of the reaction is deficient, it can be provided; (2) if the high level of substrate is toxic, the substrate can be diminished by restricting the diet, by activating its removal from the body, or by preventing its synthesis at an earlier step; (3) enzyme activity may be increased by administering a cofactor or certain drugs; and (4) the enzyme deficiency may be replaced with normal enzyme, although this approach has been successful only rarely. The ideal treatment would be to insert the normal gene itself into the cells of the patient so that normal amounts of the enzyme can be synthesized and the metabolic defect corrected directly. There are techniques for transplanting genes into animals, and they are being studied for humans.

DISORDERS OF CARBOHYDRATE METABOLISM

Glycogen storage diseases. The role of glucose as a critical source of energy for the brain and as the initial source of energy for muscles requires that it be stored in an easily releasable form. The storage form of glucose is

a large, branched molecule known as glycogen. The liver serves as the glycogen (and therefore glucose) depot for the brain, while muscles maintain a glycogen supply of their own. Glycogen is synthesized from, and broken down to, glucose as shown in Figure 14.

Types

There are at least 10 well-recognized varieties of glycogen storage diseases, all of which are autosomal recessive disorders (Figure 14). In each, glycogen accumulates in the liver or muscles and sometimes in the kidneys. In type I glycogen storage disease, the last step in glucose release from the liver is defective, leading to low levels of glucose in the blood (hypoglycemia). While hypoglycemia may not bring about symptoms in some persons, it may ultimately produce coma or convulsions in others. If the rate of conversion of the immediate precursor of glucose, glucose 6-phosphate, to lactic acid increases, acidosis (greater acidity of the blood) results. A compensatory mechanism that diverts amino acids away from protein synthesis and toward glucose synthesis (gluconeogenesis) leads to stunted growth. Treatment of type I disease consists of frequent daytime feedings augmented by glucose and protein delivery at night. This regimen protects the brain from hypoglycemia, reduces the size of the liver, and restores growth.

Defects in earlier steps in glycogen breakdown in the liver cause glycogen storage disease types III, VI, VIII, IX, and X (Figure 14), which usually lead to milder versions of type I disease. Each responds to similar treatment. In type IV disease, an abnormal unbranched glycogen molecule (amylopectin) accumulates and causes severe liver failure. In glycogen storage disease type II, an entirely separate pathway for degrading the glycogen present in cell storage organelles, called lysosomes, is defective, resulting in the accumulation of glycogen, in the heart, muscles, and liver; in severe cases this leads to early death from heart failure. In glycogen storage disease type V, the first step in muscle glycogen degradation is deficient, preventing the release of glucose. Strenuous exercise must be curtailed, and muscle cramps and even muscle damage can occur. In glycogen storage disease type VII, glycolysis (breakdown of glucose) is deficient in muscle, producing similar symptoms and an accumulation of glycogen.

(II) Lysosomal α-1,4-glucosidase (Pompe). (III) Debranching enzyme (Forbes). (IV) Branching enzyme (Andersen). (V) Muscle phosphorylase (McArdle). (VI) Liver phosphorylase (Hers, VIII, IX, X). (VII) Muscle phosphofructokinase (Tauri). (A_1) Galactokinase. (A_2) Galactose 1-phosphate UDP transferase (galactosemia). (B) Fructokinase (fructosuria). (C) Aldolase (hereditary fructose intolerance). (D) Fructose 1,6-diphosphatase deficiency. (E) Pyruvate dehydrogenase complex deficiency. (F) Pyruvate carboxylase deficiency.

Galactosemia. A classical autosomal recessive disorder, galactosemia usually is due to a defective component of the second major step in the metabolism of the sugar galactose (Figure 14). When galactose is ingested, as in milk, galactose 1-phosphate accumulates, causing severe liver damage as well as kidney abnormalities, mental retardation, and hypoglycemia. An alternative product of galactose metabolism, the sugar galactitol, is deposited in the lens of the eye, causing cataracts. A defect in the first step of galactose metabolism causes only the accumulation of galactose itself and cataracts. Early, complete, and permanent elimination of galactose from the diet prevents these adverse effects.

Fructose disorders. Fructosuria is an autosomal recessive disorder caused by a defect in the first step in the metabolism of the sugar fructose (Figure 14). Fructose is therefore excreted in the urine, but there are no other consequences and the condition is harmless. In contrast, in the autosomal recessive disorder hereditary fructose intolerance, a deficiency of a later key enzyme in fructose metabolism leads to the accumulation of fructose 1-phosphate, a toxic substance that causes vomiting and hypoglycemia initially and liver damage over a long period of time. Eliminating fructose, in the form of fruit or sucrose (table sugar), is effective treatment. Fructose 1,6-diphosphatase deficiency is an autosomal recessive disorder that prevents the synthesis of glucose from its precursors (Figure 14), causing hypoglycemia after a short period of fasting. Ingestion of fructose also causes hypoglycemia and lactic acidosis. Treatment consists of frequent feeding and avoiding fructose.

Hypoglycemia

Pyruvate disorders. Two autosomal recessive disorders, pyruvate dehydrogenase complex deficiency and pyruvate carboxylase deficiency (Figure 14), can cause the accumulation of a three-carbon metabolite, pyruvate, in the blood. As a result, the level of lactic acid in the blood rises, causing acidosis. Both disorders also cause abnormalities of the central nervous system and retardation. In addition, pyruvate carboxylase deficiency causes hypoglycemia because glucose is not synthesized (Figure 14).

Intestinal carbohydrate malabsorption. Carbohydrates are ingested primarily in the form of larger molecules, such as starch (the chief storage form of carbohydrates in plants), from which the smaller sugars eventually are produced by the actions of intestinal enzymes (oligosaccharidases), such as maltase, which splits maltose to glucose; lactase, which splits lactose (milk sugar) to glucose and galactose; and sucrase, which splits sucrose (table sugar) to glucose and fructose. Lactase deficiency is common, occurring in up to 20 percent of North American whites, and 50 to 90 percent of blacks and Asians. Although hereditary, this disorder usually does not show symptoms until after infancy. Abdominal fullness, nausea, and cramping pain with watery diarrhea follow the intake of milk products containing lactose. Similar symptoms occur with a deficiency of sucrase after the ingestion of table sugar. In these conditions, glucose levels do not increase in the blood after lactose or sucrose, respectively, are ingested. These symptoms are eliminated when lactose or sucrose, respectively, are avoided.

Mucopolysaccharidoses. Sugar molecules may come together in repeating units to form polymers known as mucopolysaccharides. When proportionately more sugar polymers are bound to a protein core, the molecule is known as a proteoglycan. When the molecule contains pro-

portionately more protein than sugar polymers, it is called a glycoprotein. All of these perform diverse functions, particularly as basic components of the material between the tissue cells (the matrix). Mucopolysaccharides are regularly degraded as part of the process of tissue renewal. If any one of 15 enzymes responsible for this degradation is abnormal, partially degraded mucopolysaccharides accumulate in the tissues, causing recessive diseases with similar characteristics (Hurler, Hunter, Sanfilippo, and Morquio syndromes). These characteristics may include short stature, various deformities of the skeleton, stiffened joints, corneal clouding, deafness, dental abnormalities, hardening of the arteries, enlarged liver and spleen, and mental retardation. These syndromes are diagnosed by analyzing the incompletely degraded mucopolysaccharides in the urine and tissues. Prenatal diagnosis is also possible. No treatment is available for any of these disorders.

DISORDERS OF LIPID METABOLISM

Blood lipid disorders. Lipid molecules, such as triglycerides and cholesterol, circulate in the blood and are bound to carrier protein molecules. In certain hereditary metabolic disorders, the levels of triglycerides and cholesterol in the blood are high because the mechanisms that remove them are defective. As a result, triglycerides and cholesterol may be deposited in the skin, tendons, and walls of blood vessels, which can lead to coronary heart disease and early death.

Familial dysbetalipoproteinemia

In familial dysbetalipoproteinemia (type III hyperlipemia, autosomal recessive), a mutant carrier protein causes the accumulation of triglycerides and cholesterol. The disease is treated by restricting fat and cholesterol in the diet and with drugs that lower the level of lipids in the blood. In familial hypercholesterolemia (type II hyperlipemia, autosomal dominant), a protein receptor on the surface of all cells, which allows cholesterol to move into the cell, is either missing or defective. As a result, cholesterol is not moved into the cells, where mechanisms are in place to register the availability of cholesterol to metabolic processes. Under normal conditions, when enough cholesterol is registered, feedback mechanisms signal the cholesterol-synthesizing enzymes to cease cholesterol synthesis. In the disease state, the synthesizing enzymes are relieved of feedback inhibition, thus inducing the synthesis of still more cholesterol. Homozygotes (one per 1,000,000 persons) have much higher levels of cholesterol in the blood than heterozygotes (one per 500 persons) and may die before the age of 20. Restricting cholesterol in the diet and drug treatment sufficiently lower cholesterol in heterozygotes but not in homozygotes. Although relatively uncommon, familial hypercholesterolemia is an important model for the association between a high prevalence of coronary heart disease and modest elevations of blood cholesterol levels, which is often found in the West. In familial lipoprotein lipase deficiency (type I hyperlipemia, autosomal recessive), the enzyme responsible for transporting triglycerides into cells is deficient. Triglycerides build up in the blood, and the blood serum takes on a creamy consistency and colour after the ingestion of fat. There is abdominal pain, inflammation of the pancreas, and enlargement of the liver, but there is no increased risk of coronary heart disease. Restricting dietary fat eliminates the symptoms.

In familial betalipoprotein deficiency (autosomal recessive), the absence of a major transport protein leads to low levels of triglyceride and cholesterol in the blood. Dietary fat and lipid-soluble vitamins, particularly vitamin E, are not adequately absorbed. Vitamin E deficiency may be partly responsible for the resulting severe dysfunction of the nervous system, the eyes, and the muscles.

In familial high-density lipoprotein deficiency (Tangier's disease, autosomal recessive), the level of cholesterol in the blood is low, while that of triglycerides is high or normal. Cholesterol is deposited in many tissues, including those of the nerves, cornea, lymph nodes, and enlarged yellow tonsils. There is no treatment.

Wolman's disease

In Wolman's disease, cholesterol esters accumulate in many tissues because the specific enzymes that cleave them are absent. Massive enlargement of the liver and spleen, calcification of the adrenal glands, failure to grow, and death in infancy are characteristic of this disease.

Lipid oxidative disorders. The oxidation of fatty acids for energy requires that they be transferred into the mitochondria by associating with a cofactor, carnitine, which is synthesized in the body. Deficiency of carnitine or of the enzyme carnitine acyltransferase (which facilitates the movement of fatty acids across the mitochondrial membrane) in muscle tissue leads to weakness and cramping with exercise. A low level of carnitine in the blood and tissues produces severe brain, liver, and heart damage. The exact defect leading to this autosomal recessive disorder is not known. Treatment with carnitine is partially effective.

Tissue lipid disorders. Complex molecules composed of long-chain fatty acids linked with various sugars, phosphate, and sulfate groups form essential components of cell membranes and are vital to the normal functioning of the nervous system. These molecules are degraded and resynthesized in the normal course of tissue turnover. Defects in the enzymes that regulate this process cause these lipid molecules to accumulate, which is associated with a number of severe autosomal recessive disorders (Figure 15).

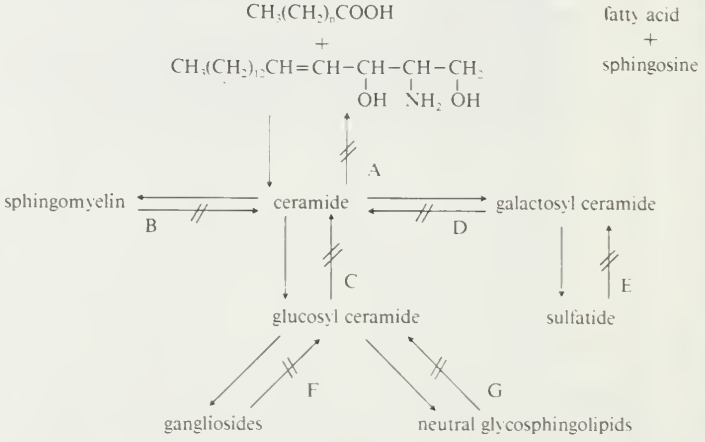

Figure 15: *Enzyme defects in tissue lipid disorders.* (A) Ceramidase (Farber). (B) Sphingomyelinase (Niemann-Pick). (C) Glucocerebrosidase (Gaucher). (D) Galactocerebroside β-galactosidase (Krabbe). (E) Arylsulfatase A (metachromatic leukodystrophy). (F) Hexosaminidase A (Tay-Sachs). (G) α-Galactosidase A (Fabry).

Among the symptoms are nervous system dysfunction and mental retardation; a unique cherry-red spot in the centre of the inner eye (Tay-Sachs disease); enlargement of the liver and spleen; characteristic foamy, lipid-filled cells in the bone marrow (Gaucher's and Niemann-Pick disease); or arthritis (Farber's disease). All but Gaucher's disease may cause early death. Fabry's disease is an X-linked disorder involving predominantly the blood vessels, kidneys, and eyes. For most of these conditions, the defective genes can be identified in carriers, and a prenatal diagnosis can be made. There is no successful treatment.

DISORDERS OF AMINO-ACID METABOLISM

Twenty amino acids, including nine that cannot be synthesized in humans and therefore must be obtained through food, are involved in metabolism. All are incorporated into proteins; some also are synthesized into important molecules in the body such as neurotransmitters, hormones, pigments, oxygen-carrying molecules, and the nucleotide bases of DNA and RNA. Each amino acid is further broken down to ammonia, carbon dioxide (CO_2), and water (H_2O). About 50 metabolic defects in amino-acid metabolism are known (Table 2), and their clinical consequences range from none to lethal.

Phenylalanine and tyrosine. The disorders involving the essential amino acids phenylalanine and tyrosine are examples of the many consequences of amino-acid dysfunction. Figure 16 demonstrates how these amino acids are synthesized and broken down into important molecules. Phenylketonuria is caused by the absence of the enzyme phenylalanine hydroxylase, which converts phenylalanine to tyrosine. Other variants (hyperphenylalaninemia IV and

Effects of phenylketonuria

V) are due to defects in the supply of the cofactor required for this reaction. Phenylketonuria produces severe mental retardation, seizures, rash, and high levels of phenylalanine in the blood and of its metabolite, phenylpyruvic acid, in the urine. Screening of blood at birth and restriction of phenylalanine in the diet are preventive measures.

Tyrosinemia results from a deficiency of the enzyme that catalyzes the first, and rate-limiting, step in tyrosine degradation, tyrosine transaminase (also called tyrosine aminotransferase). Tyrosinemia causes erosions of the skin and cornea of the eye. Deficiency in the next step causes a transient and harmless elevation of the level of tyrosine in the blood. A defect in the third successive enzymatic step causes an accumulation of homogentisic acid (which darkens the urine) and is called alkaptonuria. Although rare, alkaptonuria is of historical importance because it was Garrod's studies of this condition that led to his one-gene : one-enzyme hypothesis (one gene codes for one enzyme). When homogentisic acid is oxidized, the products are deposited in cartilage and connective tissue, producing a blue-gray colour in some areas of the skin and black discoloration in the joints; in adults, a severe form of arthritis, called ochronosis, results.

A disorder that results from a defect in the last step of tyrosine degradation, tyrosinosis, is a more generalized condition involving elevations of the levels of the amino acids methionine and tyrosine in the blood. Sudden liver failure may lead to early death; alternatively, there may be progressive kidney dysfunction in the form of Fanconi's syndrome (see below *Disorders of amino-acid transport*).

Tyrosine is a parent amino acid for skin, hair, and eye pigments (Figure 16). There are at least 10 syndromes, known generally as oculocutaneous albinism, that are

characterized by the failure to form melanin pigments, resulting in partial or complete albinism. In addition to having white hair and white skin, persons with these defects are hypersensitive to light, and they have decreased vision and aberrant control of eye muscles. Oculocutaneous albinism can be autosomal recessive, autosomal dominant, or X-linked. A defect in the first step leading toward melanin synthesis, catalyzed by the enzyme tyrosinase, accounts for some of the syndromes; in others, the site of the block in pigment production is not known. The only available treatment is to avoid sunlight and to correct vision.

Finally, tyrosine is also the precursor amino acid for hormones of the thyroid gland. Defects in this synthetic pathway result in familial hypothyroidism, compensatory enlargement of the thyroid gland (goitre), severe growth failure, and retardation of central nervous system development. Screening of newborns and replacement of deficient thyroid hormone in affected persons prevent all or most of this damage.

Urea cycle enzymes. When amino acids are degraded, the ammonia nitrogen at one end of the molecule is split off, incorporated into urea (the chief solid component of urine), and excreted in the urine (Figure 17). This process starts when an ammonia group is combined with bicarbonate and phosphate to create carbamoyl phosphate, which hooks into a metabolic cycle involving five enzymes. The cycle takes in a second ammonia group from the amino acid aspartic acid, ultimately generating the amino acid arginine from which urea is split off. Defects at any of the first four steps of the cycle may cause a sudden increase in the level of ammonia in the blood, which in the newborn causes vomiting, coma, liver enlargement, and mental retardation. Early death can result when the enzyme is almost completely absent. A defect in the fifth step produces motor difficulties and seizures beginning in childhood. Specific amino-acid supplements, drugs that remove nitrogen by combining with the amino acids glycine and glutamine, and a diet low in protein are of limited benefit.

the amino group and producing CO_2, followed by reduction. Once degraded, however, their paths diverge. There are at least 11 genetic defects in the shared and nonshared portions of these pathways (Table 2). The consequences often include acidosis, hypoglycemia, and developmental retardation. In four of these conditions, the presence of incompletely degraded products in the urine is associated with distinctive odours, similar to those of maple syrup and sweaty feet. The appropriate amino acid or acids are restricted to a level that relieves the symptoms but still permits growth. Alkali, in the form of sodium bicarbonate, is given when the acidity of the blood increases suddenly.

Disorders of amino-acid transport. Energy is required to move many amino acids from the intestinal tract into the blood or to reclaim them from the urine by special cells in the kidney. This transport of amino acids is mediated by specific carrier proteins whose structures, like those of enzymes, are determined by genes. One gene may contain the code for the carrier protein that transports several amino acids; in addition, a single carrier protein may transport the same amino acids in the kidney and the intestinal tract. Mutant proteins with decreased transport activities may prevent the absorption of dietary amino acids or cause their loss in the urine. For example, in cystinuria there is decreased intestinal absorption and increased urinary excretion of four amino acids (cystine, arginine, lysine, and ornithine). The only consequence, however, is the formation of kidney stones. The essential amino acid lysine is probably absorbed from the diet in other forms. Iminoglycinuria is a completely harmless disorder of the absorption tubules in the kidney; glycine, proline, and hydroxyproline are excessively excreted in the urine without apparent consequence. In Hartnup disease, 13 amino acids, six of them essential, are not adequately reabsorbed from the intestine and kidney because of defects in the mechanism that removes them. As a result, high levels of these amino acids are excreted in the urine. Because the levels of the amino acids are low and because they are converted to toxic products within the intestinal tract, persons with Hartnup disease suffer intermittently from rashes and neuropsychiatric disturbances. In Fanconi's syndrome, because amino acids as well as other substrates (glucose, phosphate, and minerals, for example) are not absorbed well from the kidney, they are excreted in the urine. The syndrome occurs with several metabolic diseases, including cystinosis (a disorder in which the amino acid cystine is stored in cells of most body tissues). Bone disease, disturbed growth, dehydration, potassium deficiency, and acidosis result.

DISORDERS OF PORPHYRIN METABOLISM

Porphyrin functions

Porphyrins are fluorescent cyclic molecules composed of four carbon-nitrogen rings that combine with specific metals, such as iron. These molecules, which carry oxygen in the blood (as hemoglobin) and in tissues, are also components of respiratory enzymes. Porphyrins are synthesized and degraded in the metabolic process shown in Figure 18. Defects in this process cause diseases, generally known as porphyrias, which primarily affect the skin (there is blistering on exposure to sunlight), the nervous system, and, in rare instances, the blood (rapid destruction of red blood cells). They are distinguished by the appearance of fluorescent products in the tissues and urine.

A dramatic form of porphyria is acute intermittent porphyria (AIP), which is caused by a deficiency of porphobilinogen deaminase, also called uroporphyrinogen I synthetase (Figure 18), an enzyme that catalyzes the second step in the pathway of porphyrin biosynthesis. Symptoms include abdominal pain, vomiting, muscle weakness, and mental disturbance. Porphobilinogen and its precursor, aminolevulinic acid, are found in the urine. AIP is an autosomal dominant disorder that occurs intermittently because the preceding reaction, catalyzed by the enzyme aminolevulinic acid synthetase, is the rate-limiting step in the pathway. Therefore, porphobilinogen does not reach toxic levels unless the activity of aminolevulinic acid synthetase is greatly increased by exposure to drugs, by starvation or excessive dieting, or by cyclic hormonal changes.

Red blood cells release hemoglobin (oxygen-carrying porphyrin molecules) when they die. The free porphyrins are degraded to a reddish yellow pigment known as bilirubin (Figure 18), which is transported to the liver. Defects in the mechanisms that remove and metabolize bilirubin increase the level of bilirubin in the blood and produce jaundice, a yellowing of the skin and eyes. A harmless defect in bilirubin metabolism is often seen for a short time in normal newborns and permanently in some adults. In infants without the enzyme bilirubin-UDP glucuronyl transferase (Crigler-Najjar syndrome), deposits of large amounts of bilirubin in the brain can cause severe and permanent damage to the nervous system. Treatment involves increasing enzyme activity by using the drug phenobarbitol or converting bilirubin to less toxic products by exposing the infant to blue light.

DISORDERS OF PURINE AND PYRIMIDINE METABOLISM

Nucleotide bases

Purines and pyrimidines are the nucleotide bases in DNA and RNA. They have important roles in energy transformations (for example, ATP in the TCA cycle) and in other metabolic processes (for example, uridine triphosphate [UTP] in glycogen synthesis). Figure 19 shows a simplified overview of pyrimidine and purine synthesis to the parent compounds, uridine monophosphate and inosine monophosphate, respectively, as well as the important degradative route for the latter. Orotic aciduria (autosomal recessive) results from a block in the last two steps of uridine monophosphate synthesis. It is unique as a metabolic disorder in that one gene appears to control the activity of two successive enzymatic steps. Arrested growth, mental retardation, and anemia result from the deficiency of uridine monophosphate. Treatment with the pyrimidine base uridine is effective because it can be converted to uridine monophosphate by an alternate pathway.

Lesch-Nyhan syndrome, an X-linked disorder, results from a deficiency of the enzyme hypoxanthine-guanine phosphoribosyltransferase, which reuses hypoxanthine, a

product of inosine breakdown, for purine synthesis (Figure 19). If the enzyme is absent, the amount of unused key intermediate 5-phosphoribosyl 1-pyrophosphate (PRPP) is high, and the synthesis of inosine monophosphate continues (Figure 19), resulting in more hypoxanthine and, ultimately, uric acid. The nervous system is affected, resulting in mental retardation, abnormal movements, seizures, repeated self-mutilation, and death, usually by the age of 30. If the enzyme is only partially absent, gout results from the excess uric acid that settles in tissues. Gout also is a common disorder of purine metabolism in adults of the West, but in most cases the exact biochemical cause is unknown. The common denominator of all gouty conditions is high levels of uric acid in the blood. This leads to the formation of uric acid crystals in joint fluids, causing attacks of arthritis, and in the urine, causing kidney stones. The drug allopurinol, which inhibits the conversion of the immediate precursor, xanthine, to uric acid by inhibiting the enzyme xanthine oxidase (Figure 19), is effective in preventing these consequences. Hereditary xanthinuria results from a deficiency of xanthine oxidase, but is usually harmless or, at most, associated with kidney stones formed from xanthine. (S.Ge.)
